The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, JANUARY 1, 1898.

No. 1.

ADDRESS.

GLAUCOMA FOLLOWING TRAUMATISM, UNASSOCIATED WITH DISLOCATION OF THE LENS.

Chairman's Address delivered in the Section on Ophthalmology, at the
Forty-eighth Annual Meeting of the American Medical Association,
held at Philadelphia, Pa., June 1-4, 1897.

BY G. E. DE SCHWEINITZ, M.D.
PHILADELPHIA.

In the general rejoicing of the AMERICAN MEDICAL ASSOCIATION on its fiftieth anniversary the Ophthalmic Section heartily joins, and all the more heartily because by reason of its own clean record, steady development and fair achievements, it has become a model Section of this notable gathering of American physicians and surgeons. To have been chosen to preside over its deliberations is a satisfaction for which I return my sincere thanks: to become the successor of the men who have labored so hard and so productively for the advancement of this Section and for the credit of ophthalmology is an honor I highly appreciate; to welcome you, my *confrères*, perhaps I may be permitted to say, my friends, on this occasion and on all other occasions when you shall gladden us with your presence, is a pleasure I greatly enjoy.

The Chairman's address was at one time, by the organic law of the ASSOCIATION, supposed to reflect the progress of ophthalmology during the preceding year. Happily, this custom or law, as Dr. Jackson has well observed, has become obsolete, and if the chairman has done more than make a few suggestions to the general conduct of the Section, he has contributed one of the scientific papers of the session. I am therefore constrained to follow this latter custom and ask your attention to the subject of high eyeball-tension, or acute glaucoma, following blows upon the eyeball, when such an injury is unassociated with dislocation of the lens. To introduce the topic the following case may be recorded:

Joseph H., aged 46 years, born in Germany, married, saloon keeper, consulted me Feb. 5, 1894, on account of an injury to his left eye.

History.—While chopping wood, a few hours previous to his visit, he was struck on the left eye with a large piece of wood. A medical student dressed his wounds and brought him immediately to my office.

Examination.—There was a cut upon the left upper eyelid and another upon the neighboring facial area. The conjunctiva was somewhat chemotic and slightly lacerated on its albar expansion at the outer side of the eyeball. Under the influence of a mydriatic the pupil dilated irregularly, *i. e.*, only upward and inward; downward and outward the iritic fibers were parietic and refused to respond to the drug. The media were clear; the lens was in place; the optic disc was oval, its long axis being 120 degrees; the edges were somewhat hazy and the veins full. The refraction was a low myopic astigmatism and V. equaled, without correcting glass, $\frac{1}{18}$. The optic disc of the right eye was an oval, with its axis at 30 degrees; the scleral ring was visible all around and broadened below; the edges of the papilla were hazy. The refraction, like that

of the other eye, was a low myopic astigmatism and V., without a correcting lens, equaled $\frac{1}{18}$.

The wounds on the face and eyelid were stitched and a proper dressing was applied.

February 7, 1894. Stitches and bandage were removed. The conjunctiva was still somewhat edematous; a boric acid lotion was ordered.

February 12, 1894.—V. of O. S. $\frac{1}{9}$. The pupil had regained its normal round shape, but the light reaction was somewhat sluggish. The fundus was unchanged.

February 27, 1894.—Patient was not seen in spite of positive directions, until the present date. He complained of dull vision and some lachrymation, but denied the presence of pain. V. equaled $\frac{1}{45}$, with the head tipped slightly upward. Field of vision was concentrically contracted. The nerve head was obscured by a grayish swelling, the apex of which was + 2 D., the macula being not far from Em. or slightly M. The veins were enormously distended and the smaller branches very tortuous; the arteries were about normal in size and were quickly pulsating on the disc. Tn. — ? The light reaction of the pupil was sluggish; the anterior chamber was not shallowed. The patient was sent to Dr. H. A. Hare for general examination, who reported as follows: "There is no enlargement of liver or spleen; if anything, the area of hepatic dulness is somewhat smaller than normal. The apex beat of the heart is displaced downward and to the right, and is quite forcible. After exercising there is an inconstant mitral regurgitant murmur. The tricuspid valves also seem as if they might be suspected of slight regurgitation. The aortic valves are normal, but the second sound is not quite so sharp as in the average individual. The chest shows no bulging in expansion which would indicate thoracic aneurysm. The blood vessels seem to be fairly normal; a condition of high tension does not exist. The urine is normal." Leeches to the temple, a calomel purge, iodid of potassium and, locally eserine, were ordered.

March 12, 1894.—V. equaled $\frac{1}{15}$; field of vision somewhat enlarged. The margins of the disc were clearer; there was still quick arterial and venous pulse. Tn. + 1.

March 22, 1894.—V. equaled $\frac{1}{15}$ —. The arterial pulse was unchanged; the disc margins were clearer and the beginning formation of the cup was visible. The pupil reacted sluggishly to light. Treatment continued.

April 3, 1894.—V. equaled $\frac{1}{22.2}$. Media were clear; the arterial pulse continued and the cup was still more marked, although not quite complete. Only medicinal treatment was accepted, and for the iodid of potassium strychnin was substituted. The local treatment remained the same.

May 25, 1894.—The patient was not seen again for nearly two months. He had long since discontinued his internal and local medication. V. equaled O, Tn. + 1. The optic disc was atrophic and deeply cupped (bottom of cup — 5 D., edges of disc — 1.5 D.). The vessels were crowded to the nasal side and there was a strong arterial pulse; a halo was beginning to appear, most marked upon the temporal side. The pupil was fixed. Upward and outward in the ciliary region a bluish staphyloma of moderate size had appeared.

The patient was seen once more and the ocular conditions remained unchanged.

Briefly, then, the phenomena in this case were the following: Contusion of the left eyeball, with slight laceration of the conjunctiva, but without dislocation of the lens; between the seventh and twenty-second day after the injury, the development of optic neuritis, quick arterial pulsation and slight increase in intra-ocular tension, with marked depreciation of central vision and contraction of the field of vision; at first, improvement under the influence of eserine, associated with gradual subsidence of the neuritis, the improvement lasting about two weeks; later, at the end of three weeks, renewed depreciation of vision associated with the formation of a cup in the nerve head; gradual increase in the depth of the cup and the atrophy of the nerve until (treatment having been entirely disregarded) vision was reduced to *nil*; throughout the entire course of the

affection moderate increased tension, +1, and quick arterial pulse, which persisted even when the atrophy was complete; nearly three months after the injury, the development up and out, of a ciliary staphyloma.

Remarks.—Glaucoma following an injury may be typically secondary: or it may present the clinical signs and pathologic lesions of the primary variety of the disease.

To the first of these classes, with which we are not now concerned, belong the well-known examples of glaucoma secondary to perforating wounds of the cornea, forward and lateral dislocation of the lens, puncture and swelling of the crystalline body, etc. To the second class belong several varieties:

1. Cases of glaucoma following trifling injuries, *e. g.*, a slight burn or abrasion of the cornea, or even the lodgment of a foreign body on its surface.

Under these circumstances, as Priestley Smith¹ maintains, it is fair "to assume that the eye was pre-disposed to glaucoma." He further believes that "in these traumatic cases the origin of the outbreak is probably an active hyperemia rather than a passive congestion and there is a special tendency to inflammatory exudation, but the direct cause of the high tension appears to be the same as in the more typical cases." To this category would belong such a case as that reported by C. J. Lundy,² in which an outbreak of this disease, resulting in loss of the eye, followed the sting of a bee on the conjunctiva.

2. Cases of glaucoma following contusion of the eye, either without discoverable lesion or else without marked changes which would account for the increased tension.

Glaucomas of this character have usually followed a blow upon the eye, for example, from the cork of a bottle or from a chip of wood. A case in point is one reported by W. A. Brailey³. A boy aged 14 years eight days before admission to the hospital received a blow on the right eye from the cork of a beer bottle. The pupil of the right eye was fully dilated and fixed and the tension increased to +2. Vision was 6/60; the disc a little misty. The patient was treated by the instillation of eserine and gradually the disease subsided, vision and tension improving for a time, when the eserine was omitted and the pupil again dilated and tension returned. According to the reporter there was no obvious change in the eye to account for the tension, except the condition of the pupil. When this was contracted by means of eserine the tension fell, possibly because the drawing of the iris at the periphery of the anterior chamber caused a stretching of the fibers between the spaces of Fontana, permitting a readier access of the fluids of the anterior chamber to the canal of Schlemm.

Not quite so clear a case is one reported by Ferber⁴. A patient, whose age is not given, received a contusion of the eye without noteworthy injury of the bulbus and without dislocation of the lens. A small retinal hemorrhage and exudate were also visible. As these were considered too insignificant to be regarded as the etiologic factors in the production of the glaucoma which followed this contusion, the author refers to a neuropathic element, but suggests as possible and, as it seems to me, much more likely that the contusion closed the pathways of the intra-ocular currents.

A very instructive case touching on this question

of the etiology of glaucoma after blows upon the bulbus of the type we are now considering, has been reported by Knapp⁵. A patient 29 years old was struck on the eye with a cane, and presented himself for treatment with an obliterated anterior chamber, clear media, diminished tension and a myopia of 1/7 which, when corrected, gave him normal vision. After bandaging and rest there was restoration of the anterior chamber, and with its restoration an attack of acute glaucoma, which was cured by the instillation of eserine. Knapp explains this case as follows: The injury probably produced a perforation of the corneo-scleral wall at the periphery of the anterior chamber, which escaped his notice. Now, although the sinus of the anterior chamber was obliterated by the advancement of the lens which crowded the iris against the posterior face of the cornea, glaucoma did not develop until the iris reassumed its natural position, because so long as it was pressed forward and the anterior chamber was obliterated, the aqueous humor was leaking from the insignificant corneo-scleral perforation. With the closure of this perforation and the restoration of the anterior chamber, the aqueous could no longer find an outlet through Fontana's spaces, which during the time of pressure of the iris against them, had probably become impervious. In commenting on this case, which has just been quoted from Dr. Knapp's description, this author points to the analogy between this type of glaucoma and that which follows the closure of a corneal fistula, inasmuch as the same explanation is applicable to each.

3. Cases of glaucoma following injury to the eye, either with manifest lesions in the anterior portion of the bulbus, or with ophthalmoscopic changes, retinal hemorrhage, neuritis and choroiditis.

Fortunately a certain number of eyes have been carefully examined after traumatic glaucoma from the microscopic standpoint and give an explanation of the phenomena of increased tension. Priestley Smith⁶ enucleated the right eye of a woman aged 57 years, which was in a condition of acute absolute glaucoma as the result of a blow from a cork escaping from a soda-water bottle, the accident having occurred nine weeks previous to her examination. After giving the microscopic examination of the eyeball in detail, this author sums up his case as follows: "The iris had been manifestly driven forward and its periphery pressed against the cornea by the processes so as to close the angle of the anterior chamber and cut off all access to Schlemm's canal. It is likely that the blow, the violent effect of which upon the ciliary structures was indicated by a partial detachment of the iris, had caused a vasomotor paralysis and hence a congestion and swelling of the processes, and that this swelling had closed the outlet of the anterior chamber and established the glaucoma."

⁶ The Ophthalmic Review, London, 1882, I, 273-279.

In other words, in this case the pathologic changes were similar to those which are found in acute primary glaucoma.

Garnier⁷ saw in a 14 year old boy, after a blow on the eye, an acute elevation of the intra-ocular pressure, and after ten days the development of a scleral staphyloma. The ball was enucleated and microscopically there were found fluidity of the vitreous; hyperemia of the iris; widening of the veins of the canal of Schlemm; rupture of the zone of Zinn downward and inward, although the lens, which was clear, was not luxated; hyperemia of the retina; blood extravasations between the nerve-fibers of the papilla and the retina; widening of the larger vessels of the ciliary body and corresponding to the rupture of the zone of Zinn, a tear in the circular portion of the ciliary muscle, in the neighborhood of which the arterioles were thrombosed. The choroid and suprachoroid were greatly swollen and edematous and the pigment macerated, all spaces in the sclera and all perivascular lymph spaces being choked with pigment cells. To this condition of the choroid and its consequences Garnier attributes the elevation of intra-ocular tension.

In my own case, the primary irregularity of the pupil suggests lateral dislocation of the lens, but as the pupil was in a few days restored to its normal circular form and reaction (although the latter was somewhat sluggish), it may be regarded as an example of partial traumatic mydriasis, perhaps associated with a slight tear in the sphincter of the iris, although this could not be demonstrated. With the exception of this condition, which was temporary and which disappeared before the onset of glaucoma, and the slight laceration of the conjunctiva there was no demonstrable lesion in the anterior portion of the eye. The interesting manifestation which antedated the glaucoma, or rather which may be regarded as its first stage, was the optic neuritis. Now, although textbooks do not commonly describe optic neuritis as an antecedent of glaucoma, there are many observations which indicate that inflammation of the optic nerve frequently, if not always, precedes the development of glaucoma, and some authors speak with confidence of a glaucomatous papillitis⁸. It seems likely, on the basis of a number of microscopic observations, notably one by L. Webster Fox and W. A. Brailey⁹, that inflammation of the nerve may travel forward and finally invade the ciliary muscle; or perhaps that both structures, viz., the optic nerve and the ciliary muscle may be simultaneously affected. No doubt the blow upon the eyeball of my patient produced congestion and swelling of the ciliary structures, which as in the case already quoted from Priestley Smith, closed the outlet of the anterior chamber and helped to establish the glaucoma. Either as part of this process, or else antedating it, there were inflammation of the optic nerve and softening of its structures by inflammatory exudate, which rendered the cupping and atrophy all the more certain. The late development of the ciliary staphyloma, as in Garnier's case already quoted, indicates serious structural changes in the ciliary area, which permitted gradual bulging of the ocular coats in this region in consequence of the increased intra-ocular tension.

The evident conclusion of the whole matter is this, that in cases of traumatic glaucoma, setting aside for the moment those which cause the typical secondary variety of the disease, the lesions, so far as we may judge from microscopic examinations, are similar to those which we find in the primary variety of the affection. These cases further indicate the necessity of keeping under observation patients who have suffered from blows on the eye, even when all external manifestations of the injury have passed away, because there may develop, as in my own case and in many others in literature, a glaucoma which will result in blindness, if the opportunity is not afforded to treat the patient, either because he does not present himself in time, or having presented himself in time, he neglects advice and disappears from observation until it is too late to remedy the evil.

ORIGINAL ARTICLES.

THE ROENTGEN RAY IN OPHTHALMIC SURGERY.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY HOWARD F. HANSELL, A.M., M.D.

PHILADELPHIA, PA.

The discovery of Roentgen, that the soft tissues of the body were transparent to certain rays emitted from a vacuum tube when electrically stimulated, and its practical application to the uses of medicine and surgery mark a distinct epoch in the history of science. Experiments conducted by scientists the world over immediately confirmed the announcement of the mystic properties of the Roentgen or X-rays, and during the eighteen months that have passed continued experimentation has increased its applicability, widened its field of usefulness, defined in part its capabilities and limitations, and has given us every reason to believe that further research with improved apparatus and with a more profound knowledge of their intimate nature, will lead to still greater achievements. We may hope, for example, that by varying intensities of energy, or diminished duration of exposure or modification of the vacuum tubes, to inspect with some degree of clearness, the contents of organs of which we now barely see the outlines, to differentiate diseased from normal structure and to give to the X-ray the prominent place in medicine that it now occupies in surgery.

The attention of ophthalmologists was practically drawn to the utilization of the Roentgen process in ophthalmic surgery in the detection of foreign bodies such as glass and fragments of metal, in the interior of the eyeball, by the papers of Clark and Williams¹ which announced for the first time that the coats of the ball are penetrable by the rays, and that the presence of foreign bodies can be diagnosed by their shadows cast on negatives and developed by the ordinary photographic processes. In Clark's case the metal, the presence of which had hitherto been extremely uncertain, was discovered to be behind the iris near the corneoscleral angle. It was extracted by the Hirschberg magnet and the patient recovered almost the full acuity of vision. The method of using the apparatus was original and novel. A photographic film encased in water-proof covering, was inserted into

⁷ Jahresbericht f. Ophthalmologie, xxii, p. 341.

⁸ For a full discussion of this subject consult "Glaucoma: Its Symptoms, Varieties, Pathology and Treatment," by Alexander Stirling, *Annals of Ophthalmology and Otology*, Vol. v. No. iv, p. 1026; *Ibid*, Vol. vi, No. 1, p. 47.

the nostril of the same side as the injured eye until its upper extremity lay in contact with the cribriform plate of the ethmoid bone. The Crookes' tube was stationed in front and to the same side of the head about thirteen inches distant from the eye. The rays passed through the envelopes of the eye, the nasal bone, the nasal process of the superior maxillary bone and the soft tissues, casting well-defined shadows of the bony parts and of the piece of metal. The diagnosis and cure were effected by the one force under two widely different manifestations. Williams's result in determining the applicability of the rays to the diagnosis was equally satisfactory, but unfortunately the severe accident destroyed both the sight and the ball. The patient was laid on his side on a table with the temple in contact with the glass plate and the tube held obliquely thirteen inches above and in front of the face. The rays pierced the eye, its adjacent soft tissues and the bones of the external wall of the orbit, the last casting its clearly defined shadow together with that of the foreign body, both readily distinguishable from other shadows on the plate. The history of the injury showed that the offending substance was copper, therefore the use of the magnet was precluded. The eye was enucleated and the diagnosis proven. It is interesting to observe that the different methods of experimentation resorted to in these two cases demonstrate respectively, that the nasal and temporal walls of the orbit offer no practical obstacle to the applicability of the Roentgen process in ophthalmic surgery, and that both results disprove the earlier experience that the ocular envelopes themselves cast shadows so dense that that of a fragment of metal would be concealed².

The good work inaugurated in Columbus and Boston has been continued in Philadelphia with uniformly successful result. The labors of Stern in the polyclinic, of Goodspeed and Leonard in the university and of Sweet in the private laboratory of Queen & Co. have met with pronounced success. To the first named of the gentlemen I am indebted for excellent skiagraphs of the two cases reported below. After repeated experiments according to the methods of Clark and Williams, Dr. Stern succeeded by the simple device of bandaging the sensitive plate to the temple on the side of the wounded eye, allowing the patient to sit upright and suspending the tube in front of and to the opposite side at an angle of 45 degrees and fourteen inches distant, in obtaining pictures that showed beyond question the existence of foreign bodies within the ball. These are the first two successful cases in Philadelphia and demonstrate the claims previously made that the X-rays are an useful adjunct to the diagnostic resources of the ophthalmic surgeon.

During the past winter, with the able co-operation of Dr. Stern, I made a number of efforts to determine whether the rays had a beneficent or injurious effect on diseased and healthy eyes. It was found in cases of opacity of the media such as leucomatous cornea, capsular and lenticular cataract, that no improvement whatever could be noted either in the disease or in the ability of the patients to see clearer through the fluoroscope than without it. In a case of nearly absolute central scotoma due to a large patch of central retino-choroiditis, repeated exposure to the rays as they were emitted from the tube gave the same negative result. The findings in cases of atrophy of the optic nerve were equally discouraging. From these

trials it was concluded, as a means of treatment of diseased conditions causing blindness, the rays were of no value. The only exception that I am able to make to this statement is recorded in the history of Case 1, when the exposure had the unexpected effect of soothing pain and reducing inflammation, but whether this happy result was simply a coincidence or a real or psychic manifestation can not be asserted. Dr. Wilkinson of the California School for the Blind, selected six pupils for testing, one with destruction of the anterior part of each eye from an old traumatism, one with complicated congenital cataract, one with partial phthisis bulbi from ophthalmia neonatorum, and three with optic nerve atrophy. In none did the rays assist the vision in the slightest degree. Beck³, in speaking of the possible curative effects of the rays in zymotic diseases, states that the vitality of pathogenic bacteria is not impaired even after an exposure of several hours. As bearing on the subject of the sedative action of the rays mentioned as occurring in my first case, the report of their effect⁴ on frogs is of interest. A frog was placed in a small wooden box toward which the rays were directed, while a control frog in a similar box was protected from the rays by a sheet of lead laid on top of the box. To each was administered .04 mg. of strychnia; the first showed no trace of intoxication, while the latter was found in tetanic convulsions. Bock's⁵ suggestion that if persons blind from want of transparency of the media might be able to read letters painted on a card-board, that were varnished and dusted with powdered metal if they were subjected to the action of the X-rays is impracticable unless a fluoroscope or some other impossible tungstate of calcium screen by which the shadows were rendered visible be placed behind the opaque cornea or lens. Otherwise this source of illumination is no more available than any other.

No cases of injury to the tissues of the eye from the action of the rays has been published even under the former prolonged exposures, and now with improved apparatus the danger of burning the skin or producing destruction of the hair bulbs is insignificant.

Case 1.—R. G., machinist, 25 years of age, applied at the out-patient department of the Jefferson Hospital in October, 1895, with the history of an injury to the left eye while breaking a cast iron elbow with a hammer. The cornea presented a small, irregular cicatrix. The anterior capsule and the lens had commenced to opacify. The iris was inflamed and adherent to the capsule and vision was greatly reduced. No foreign substance could be seen in the imperfectly illuminated media or fundus. Under treatment the inflammation subsided and no operation was resorted to. The man was requested to return frequently for inspection. No severe symptoms developed, although the eye was subject to attacks of irritation until October, 1896, one year later, when irido-cyclitis supervened. The patient was now subjected to the X-rays, and after most creditable perseverance Dr. Stern succeeded in obtaining a shadow picture that showed the presence of a piece of metal probably located in the anterior portion of the vitreous body. It is interesting to note that one of the exposures was made during an attack of irido-cyclitis. The patient voluntarily stated that the pain was promptly and entirely relieved, and it was observed that the marked injection was greatly reduced. After an unsuccessful attempt at extraction by the Hirschberg magnet the ball was enucleated. Upon section, a scale of iron 2 mm. in length, $\frac{1}{2}$ mm. in width, was found firmly imbedded in the ciliary body and surrounded by a mass of exudation.

Case 2.—F. N. was admitted to the wards of the Jefferson Hospital Nov. 14, 1896. While chiseling a cast-iron staircase he received a wound in the left eye. The skin and cartilages of both lids, particularly the lower, were the seat of ragged wounds. The conjunctiva was cut; the cornea opened in its

³ Trans. Pan-Amer. Cong., Mexico, 1896.

⁴ St. Peters, med. Woehens., No. 1, 1897.

⁵ Memorabilien, February, 1897.

oblique diameter; the iris protruded in part through the wound in the cornea: the lens had escaped, part of the vitreous was lost and the anterior chamber was full of blood. The edges of the wound in the lid were united by suture, the torn iris and protruding vitreous cut away and the eye antiseptically dressed and bandaged. The patient asserted positively that the iron inflicting the injury was too large to be lodged within the ball and from the extent of the superficial wounds I was inclined to concur in this opinion. After a week's vain effort to save the ball the X-rays were applied and the eye enucleated. No sections of the ball were made until after Dr. Stern's skiagraph showed positively the presence of a large piece of metal in the vitreous. Subsequently a fragment of cast-iron weighing 3 grains, of irregular shape and with very sharp jagged edges, was found in the anterior portion of the vitreous.

Thus in two instances, in October and November, 1896, respectively, skiagraphy demonstrated beyond question the presence and approximate location of pieces of metal within the eyeball. In the one the condition had been assumed, in the second, the earlier diagnosis had been proven incorrect.

The next two cases in Philadelphia, reported by Ring and de Schweinitz before the Ophthalmic Section of the College of Physicians, and published in its "Transactions," Jan. 19 and Feb. 16, 1897, may be briefly referred to. In Ring's case, a piece of steel had penetrated the vitreous eighteen months before. Two radiographs were exhibited, showing the presence and probable site of the foreign body. The Hirschberg magnet was powerless to dislodge it from its bed in the ciliary body and the ball was enucleated. De Schweinitz succeeded in establishing the diagnosis by the rays, in extracting the metal after two futile attempts by other surgeons and in restoring useful vision. The following case, the last of the published series in Philadelphia, was reported before the same section in February, 1897, by Dr. A. G. Thomson. A small piece of steel had lodged in the posterior portion of the lens in a young man. Because of the continued transparency of the lens some doubt was felt as to the nature of the foreign body. A series of skiagraphs taken by Dr. W. M. Sweet, demonstrated beyond question that the foreign substance was impenetrable to the rays. Dr. Wm. Thomson subsequently extracted the lens and with it the supposed metal. Following Dr. Thomson in his detailed description of the treatment of the case read before the Amer. Ophthal. Soc. May, 1897, Dr. Sweet demonstrated his method of localizing foreign bodies in the eye, which has proven, both in this case and in others not yet published, accurate and of great value. Dr. Chas. A. Oliver reported at the same meeting, the results of his own and Dr. Leonard's methods of localization based on practically the same principle as that described by Sweet.

It is evident, therefore, that the Roentgen process, even at this comparatively early period in experimentation, while our knowledge of the properties of the rays is limited and immature, is an extremely valuable means of diagnosis in the surgery of the eye, and it is believed that continued investigation will not only confirm the claims and statements made in this paper, but will add to our conviction that in the X-rays we have an accurate, reliable and speedy method of establishing the presence or absence of foreign bodies in the eyeball.

Resignation of Professor Forel.—The celebrated alienist, Forel, has resigned the superintendency of the asylum at Burgholzi, and also announces that he will soon retire from his professorship at Zurich, in order to devote himself entirely to his studies of comparative anatomy, especially anatomy of the brain.

THE ROENTGEN RAYS IN OPHTHALMIC SURGERY.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY WILLIAM M. SWEET, M.D.

PHILADELPHIA, PA.

The value of the Roentgen rays as a means of determining the presence of pieces of metal in the eyeball has been conclusively shown by the experiments of a number of investigators, the earliest workers in this field being Dr. Clark of Columbus, Dr. Williams of Boston and Dr. Max J. Stern of this city. The knowledge that a foreign body is in the eye, however, is not all the information required by the surgeon who operates with the electromagnet for its removal. Without some indication of the position of the body, it is not possible to reduce the percentage of failures of the magnet operation. The ordinary radiograph does not accurately indicate the position of the shadow of the foreign body on the plate in relation to the shadows of the bones of the head. Hence it is desirable to state the exact spot at which to insert the magnet with the least injury to the structures of the eye.

The first attempt to determine the approximate location of foreign bodies in the eye by means of metal indicators placed without the ball, was made by Dr. H. Lewkowitch, and reported in the London *Lancet* for Aug. 15, 1896. In these experiments, which were made on sheep's eyes and the doctor's own eyes, the indicator consisted of a piece of wire placed in front of the eye, one of the arms of the apparatus pointing to the center of the cornea. Only the anterior portion of the eyeball was included in the radiograph, the eye being rotated inward or outward to include a larger part of the globe. The determination of the position of the foreign body was then made by a triangulation of two shadows on the plate cast by the foreign body, by moving the tube a known distance from the first position in making the second exposure. The photographic plate was placed at the inner canthus. In addition to these complications, and the liability of error in determining the angles of the tube in its two positions with the plate and the foreign body, the method is open to the objection that only a small portion of the eyeball is included in the radiograph.

In my early experiments with pigs' eyes placed in the ordinary Viennese mask, it was found that unless the rays were passed through some portion of the bony walls of the orbit, foreign bodies in the posterior portion of the vitreous chamber could not be shown.

In the first experiments which I made upon the human subject, the photographic plate was inserted at the inner canthus. Photographic films were used, as being more readily cut to the shape desired. Each plate-holder carried two films, and two negatives were thereby secured at each exposure, thus avoiding errors arising from imperfections in the film coating.

The indicating apparatus consisted of an aluminum frame, carrying three steel rods, each with a rounded end. The rounded extremities were adjusted to the inner and outer canthus and to the eyeball at the center of the upper lid. Two exposures were made, one with the Crookes' tube on a line with the inner and outer indicators, and the other below the horizontal plane of these indicators. In determining the position of the foreign body in the eye, the apparatus was attached to a fixed support and a lighted candle

employed to cast the shadows of the indicators on a card board similarly to those made on the negatives by the X-rays. A small object was then held in such a position that its shadow was identical with that of the foreign body. The candle was moved until the shadows of the indicators corresponded to those on the second negative. The crossing of the two lines of shadow of the test object represented the situation of the foreign body.

This method of marking was first employed in the case of a young man with a piece of steel in the lens, sent to me by Dr. A. G. Thomson. From a number of negatives I located the body 7 mm. behind the center of the cornea, and about a millimeter to the nasal side. Dr. William Thomson subsequently removed the soft and opaque lens with the piece of steel imbedded in it.

While the use of the photographic plate at the inner canthus has the advantage of bringing the sensitive film much closer to the eyeball than when in any other position, an important consideration when dealing with very small objects, it has the objection that the whole eyeball is not included on the plate. For this reason, and also because of the imperfect coating of the celluloid films, I have since used glass plates bandaged to the temple. Instead of three indicators, two only are now used.

The principle of employing two objects of known position to locate the situation of a third object from the shadows cast by these objects upon a flat surface, is extremely simple. For all practical purposes we may regard the rays from a Crookes' tube at least thirteen inches away, as being parallel in passing through a body as small as the eye. Therefore if the relative position of two objects is known, we can readily determine the situation of the third. In employing this principle in locating foreign bodies in the eye, three factors are of importance, viz., that the two indicating objects shall be at a known distance apart, and shall be parallel to each other and to the plate, and also in a perpendicular line with the plate; that one object shall point to the center of the cornea and be at a known distance from the eyeball; and that the visual axis shall be parallel to the indicators and to the plate. With the above facts known, the angle of the tube with the plate is unimportant.

The indicators may be supported by a headband and the plate held in place by an ordinary bandage, although more accurate results are obtained by employing a special form of apparatus, in which the indicators are attached to the plate holder, and are at all times parallel to each other and to the plate. The indicators are adjustable, so that one may be placed opposite the center of the cornea while the other is toward the outer canthus.

In making the negatives the tube is in front, about thirteen inches from the plate and at an angle of from 15 to 40 degrees with a vertical plane passing through the apex of each cornea. The plate is to the opposite side of the head and the rays pass through the eyeball and the external orbital wall before reaching the sensitive film. Two exposures are made, one with the tube in a horizontal plane with the two indicators and the other at any distance below. The angle of the tube below the horizontal is unimportant so long as the two exposures give different relations of the indicators on the negatives.

In determining the position of the foreign body in the eye, two circles, 24 mm. in diameter (equivalent

to the size of the globe) are drawn upon paper. One circle represents a horizontal section of the eyeball and the other a vertical section. Upon the vertical section a spot is made at the center of the circle, indicating the position of the central indicator of the

Indicating apparatus supported by head band, and plate held in place by bandage.

apparatus. The distance between the two indicators is measured toward the temporal side and a spot made to show the position of the external indicator.

On the circle representing a horizontal section of the eyeball, a spot is made anterior to the center of the cornea and at the same distance that the center

Plate-holder, with indicating apparatus attached.

indicator was from the eye when the radiograph was made. Another spot to the temporal side, measured by the distance between the two balls of the apparatus, marks the situation of the external indicator.

By taking the first negative with the tube horizon-

tal to the two indicators, we measure the distance of the foreign body above or below the two balls of the apparatus. These measurements are indicated on the circle representing the vertical section of the eye and a line is drawn through the points. At some point along this line is situated the foreign body. From the second negative made with the tube below the plane of the two indicators, the measurement is taken of the distance the shadow of the foreign body is above or below the center indicator, and this point is indicated on the first circle. The same measurements are made for the external indicator. Where a line drawn through these two points crosses the line of measurements made from the first plate is the situation of the foreign body as respects its horizontal and vertical position in the eyeball.

Diagrammatic circles of the eye, upon which measurements from the negatives are made to show location of foreign body. Upper circle, horizontal section; lower circle, vertical section of eyeball.

To determine the distance of the foreign body behind the apex of the cornea, one of the negatives is taken and a measurement made of the distance the shadow of the center ball is posterior to that of the external ball. The distance is entered directly above the external ball on the diagram representing the horizontal section of the eye. From this point a line is drawn through the ball of the center indicator, which indicates the direction of the rays from the tube when the exposure was made. Taking the plate again, we measure the distance that the shadow of the foreign body is back of that of the external indicator. This distance is marked perpendicularly to the spot representing the ball of the external indicator on the diagram and a line is drawn parallel to the direction of the rays from the tube. Where this line cuts a line

perpendicular to the position of the foreign body shown on the vertical section of the eyeball is the distance the foreign body is behind the anterior portion of the cornea. Where the foreign body is outside the eyeball, this fact will be indicated by the crossing of the lines beyond the diagrammatic circles.

The first patient upon whom I employed this method was a young man, 20 years of age, a machinist by occupation. Six months prior to coming to Wills Eye Hospital a piece of steel struck him in the left eye. Dr. William Thomson referred the case to me

Outline drawing of negative made with tube nearly horizontal with plane of indicators.

to determine the presence of a foreign body and its probable location. Examination, in April, 1897, showed a scar in the sclera, 3 mm. from the corneal margin on the temporal side, starting from the hori-

Outline drawing of negative made with tube below horizontal plane of the two indicators.

zontal plane and extending downward, almost vertically about 4 mm. The ophthalmoscope failed to reveal the presence of a foreign body but showed a cone-shaped mass of new tissue extending through the vitreous, with the apex at the disc. The visual field was lost centrally and to the nasal side, but partially preserved downward and outward.

A number of radiographs were made with the Crookes' tube in various positions and in each of the

negatives the shadow cast by a foreign body was plainly visible. The two indicators in each exposure were 12 mm. apart, while the ball of the center indicator was 4 mm. from the apex of the cornea. The external indicator was inadvertently placed 2 mm. nearer the eyeball than the center indicator. This difference is allowed for on the diagrams. The exposures averaged four minutes each. Employing the method previously described, the measurements from the negatives indicated the position of the center of the foreign body to be a point 20 mm. from the center of the cornea, 5 mm. to the temporal side and 3 mm. below the horizontal plane. The negatives also gave the probable size of the body to be 4 mm. long, 2.5 mm. wide and 1 mm. thick.

In reporting the case at the Washington meeting of the American Ophthalmological Society, Dr. Thomson stated that, owing to the mass of tissues surrounding the body it was found to be impossible to remove it by the magnet and that recourse was had to dissec-

sitated at a point corresponding to the tissue covering the outer and upper crest of the orbit. The other foreign substance was in the skin of the nose. The man has failed to appear since the negatives were made, so that no opportunity was furnished to verify the findings.

I also employed the rays on a patient sent to me by Dr. Jackson, who presented the history of a piece of metal flying into the eye twenty years ago. Ophthalmoscopic examination by Dr. Jackson and by many other gentlemen at the time the case was shown at a meeting of the section on ophthalmology of the College of Physicians, showed a dark mass lying to the temporal side of the disc, about one-half millimeter long and one-third millimeter in width, in an area of atrophied choroid and pigment deposit rather smaller than the disc.

Notwithstanding that over a dozen negatives were made of the case at different times with Crooke's tubes running under various degrees of vacuum and

Radiograph. John Routledge. Tube below horizontal plane of indicators. Exposure four minutes. Queen Self-regulating X-ray Tube.

tion. The body was extracted with some of the cicatricial mass surrounding it from a point in the sclera corresponding to that shown in the diagrams made from the radiographs.

The second patient from whom radiographs of the eye were obtained came to the Polyclinic Hospital to have a piece of steel removed from the surface of the cornea. Dr. H. F. Hansell noticed that the right lens was opaque and, suspecting a foreign body in the eye, asked me to make some X-ray pictures. The man, a machinist by occupation, stated that he had been blind in the eye for several years and had never suffered any pain or irritation from it. A number of negatives were made, and in each instance two shadows made by foreign bodies were shown upon the plates, one in the region of the eye and the other about an inch below the eye. There was every reason to suspect that one of the bodies was in the eye or in the orbit, but upon employing the system of measurements previously described with several sets of negatives, the body in every instance was shown to be

placed at various positions, no evidence of a foreign body was shown on a single negative.

The failure of the Roentgen rays to show on the photographic plate the presence of a foreign body in the eye of the patient of Dr. Jackson, when the ophthalmoscopic examination apparently indicated the existence of a body in the eye, led me to make a number of experiments on the cadaver to determine if possible:

1. Whether very small metallic bodies in the eye could be located by means of the Roentgen rays.
2. To what extent the bones of the orbit interfered with the passage of the rays.
3. The character of the tube and the vacuum at which it should be operated to give the best results.
4. The best point at which to place the tube.

Experiments were made in the pathologic laboratory of Jefferson Medical College on a fresh, well-developed male subject. The shrunken eyeballs were removed and fresh pigs' eyes employed in which pieces of iron had been inserted. In this way the nearest

approach to the ordinary conditions met with in the live subject was secured.

In making the experiments exposures were made with two forms of the Queen self-regulating X-ray tube. In one tube the rays from the concave cathode focused to a small point on the platinum plate, while in the second tube the focus was larger. In one of the pig's eyes a piece of fine wire was passed through the center of the globe in its antero-posterior diameter. In another pig's eye three pieces of wire, about one and one-half inches long, were inserted in the nasal half of the pig's eye, entering it at the corneo-scleral margin and passing through the ball to the retina. The wires were respectively .9, .5 and .3 mm. in diameter. The largest piece was partially cut through at intervals of 1 mm. In a third pig's eye, pieces of iron were inserted in the ball, each about 1 mm. long and varying in thickness from .3 to 1 mm. The bodies were inserted in the eye at the nasal side. A number of exposures were made with each tube, several at an angle of fifteen degrees with a vertical plane passing through the two eyes, and a number at an angle of about forty degrees in front of this plane.

Radiograph. John Routledge. Tube nearly horizontal with plane of indicators. Exposure four minutes. Queen Self-regulating tube.

These experiments seemed to leave no doubt as to the great superiority of the small focus point tube as compared with that of large focus. The shadow of even the finest wire is distinctly shown on the negatives made with the former, while in those made with the latter, the shadow of the wire is blurred and indistinct. This is in harmony with the well-known fact that the distinctness of the shadow of an object some distance from a plane surface depends on the size of the source of light, and where the point of illumination is large, as compared with the size of the object, the shadow cast may be indistinct or even imperceptible.

The negatives also show to what small degree the bones of the orbit obstruct the rays. The thickest portion of the external orbital wall is where the frontal and malar bones join, forming the external angle of the orbit. In the deeper portion of the orbital wall the bones are relatively thin. Notwithstanding the difference in the thickness of the bones, the shadows cast by the steel wires are perfectly distinct throughout their entire length. In making radiographs of the eye, the

best results are secured when the tube is run at high vacuum, so that there shall be great penetration of the ball and the muscular and bony structures. In this way the shadow of the denser metallic body is more clearly shown upon the plate.

In the experiment with the small bodies in the eye, the superiority of the small point focus tube for eye work was again shown. The exposures made with the large point focus tube failed to show any shadows on the plates of the bodies in the eye, while in the negatives made with the small point focus tube, each of the five foreign bodies can be clearly seen. In dealing with the live subject the possible slight movement of the head during the exposure is a factor of importance.

In my experiments I have used several makes of Crookes' tubes, although the majority of the exposures were made with the Queen self-regulating tube. In this tube by an ingenious arrangement of a shunt circuit, the current passes around the tube when the vacuum becomes too high, heating up an auxiliary bulb of potassium hydrate and bringing down the vacuum. The gap in the shunt circuit may be adjusted to any desired vacuum, and the tube then runs automatically, irrespective of the length of exposure. The time of exposure was varied from two to six minutes, four minutes appearing to give perfectly satisfactory results, although in one instance an exposure of thirty-five seconds gave a negative of excellent detail.

Both X-ray plates and rapid landscape plates were used in the experiments, and so far as could be seen from the negatives, the landscape plates gave as good detail and as sharp outline of the foreign bodies as those made with specially prepared X-ray plates, besides which the landscape plates required much less time in developing and fixing.

In carrying out the experiments, Queen & Co. of Philadelphia kindly placed at my disposal their X-ray laboratory, with full facilities for testing the value of various forms of tubes and apparatus. Throughout the work I have had the assistance of Mr. H. Lyman Sayen, the expert of the laboratory, whose help has been of value in contributing to the success of the experiments.

DISCUSSION.

Dr. C. F. CLARK of Columbus—The only two points I can take up that are perhaps of some importance, and which have not been dwelt on very thoroughly, are questions as to the method and as to possible accidents. The question of holding the plate in the angle of the eye has been touched on. That is the method I found most satisfactory in the first case I had; it was a very minute piece of metal imbedded in the base of the iris and it was impossible to locate it without this method. Every other method had been tried. The patient had good vision and I could get a perfect view of the fundus, and though there was a chance to save the eye, and I did save it. If I had used the ordinary method I believe I would have failed. I held the plate next the nose for eight minutes while the patient sat in the chair, and it proved very satisfactory. The piece of metal was 1.5 mm. thick.

As to accidents, I heard a paper by Dr. Scott of Cleveland, not the oculist, but a physician there who had found, in recording the cases given throughout the country, some fifty or sixty cases of accidents from the use of the Roentgen rays. In one of my cases, which I made no report of because the result was negative, the patient came back with the usual result as shown on the skin. A dermatitis had set up, the hair over the whole exposed region had fallen out and though it returned after a few months it was white. Dr. Scott says he has found that these accidents occur with every form of apparatus and in whatever way it is used. All the precautions now known may be taken and still this may result. The apparatus we used was perfect and yet a few weeks later his

wife remarked that "the barber had cut his hair too close," and when finally he came to me the head was absolutely bare at the exposed points.

In regard to the method, I tried some experiments with inserting the plate into the nose, getting the thin bones of the ethmoid as the only resistance. I do not know whether it can be retained long enough to take a good picture.

Dr. MAX J. STERN of Philadelphia—At the request of my friend and colleague, Dr. Hansell, I undertook a series of experiments last year, and developed our present method of taking the pictures. I recognized that the simpler this method is made the better the results must be. The way I started out was to bandage the plate to the side of the head and I have determined that that is by far the best way to take them. I allow the plate to overlap the face one or two inches, tilting it a little forward. The exposure has been reduced from forty or forty-five minutes to one-half a minute, which I now consider sufficient. I have now been using the higher vacuum tubes which give a much shorter definition and better penetration, and one-half minute is sufficient to get a foreign body anywhere in the eye. The tube is always placed eight inches from the face.

The admirable pictures shown by Dr. Sweet certainly shows his to be a good method, but I never used it because I believe that the shortness of the image and a knowledge of the anatomic points will, in the majority of cases at least, give the location of the body. There are two planes always shown in these pictures, the one at right angles to the other, and with these and the known location of the tube the object can be located. The closer the object to the plate the clearer will the shadow be, and the greater the haziness the further is the object from the plate. I always fix the patient's eye in a line with the pin point from which my X-rays emanate. A body seen directly in that line will show the plane in which the object lies. In this way the diagnosis can be made as to position. In Dr. de Schweinitz's case the location was pointed out, the body cut down upon and removed. The same was done in Dr. Hansell's case.

Dr. LUCIEN HOWE of Buffalo—After such an excellent presentation as we have had I hesitate to show such imperfect work as I have done; still there is one point which one of the pictures illustrates that has not been touched upon. I present these two pictures [passing them]. The first one shows two rabbit's eyes, a needle having been passed through one with the object of showing how distinctly the object could be traced. The second was an attempt to ascertain the relative opacity of different portions of the eye. Taking the eye of the hog and putting it in the curtain ring and having the rays come down upon it I thought I might get some hint of the relative opacity. It was imperfect but shows that the lens region is the most opaque.

Dr. ALBERT B. HALE of Chicago—I want to report one failure in the use of the ray. It was similar to the experiment just reported. The case was that of a girl of 20 years, who, several years ago, had one discision performed for a high grade of myopia. She had never gone back for another examination. When I found her the vision was very much reduced in that eye. Ophthalmoscopic examination showed the iris adherent to what was left of the capsule in an irregular way, but there had been no great iritis. In order to see what the lack of vision was due to, I had a photograph taken, which showed very distinctly the opacity of lens substance as mentioned by Dr. Howe. The question occurred to me, has the lens matter left there become opaque or has the vitreous become atrophied and induced atrophy of the retina. There was distinct opacity where the lens ought to be. Encouraged to think it was the lens, and that if removed rays of light might pass more readily, I did a very thorough discision. With the ophthalmoscope you could see very much further in toward the fundus. But there was no improvement of vision.

Dr. A. N. ALLING of New Haven—I am interested in these papers because I made a few experiments and came to the conclusion that it was possible to locate a body by these means. I must say, however, that I think cases in which this is a great help are extremely rare, that is, where our treatment of the case would be modified by the result of this experiment. It is of scientific interest more than of practical service.

Dr. J. A. LIPPINCOTT of Pittsburg—I would like to report briefly a case of this kind where I obtained a very satisfactory skiagraph of a body in the lower part of the eyeball. The case was an easy one, as the foreign body was large, being 2 cm. long and 1 cm. thick. Its position was satisfactorily demonstrated and we were enabled to extract it with a powerful magnet.

Dr. WILLIAM THOMSON of Philadelphia—In regard to the value of diagnosis in this case of Dr. Sweet, the wound of entrance was in the ciliary region and when I saw the man, vision

was almost entirely lost. The media were transparent to the inner half, but to the outer part you could see a connective tissue deposit about the wound of entrance and back of that the retina seemed to be separated and there was a distinct tract of connective tissue in the vitreous. The papilla could be distinctly seen and the vessels were swollen. I became satisfied that it was impossible to gain any further knowledge of the condition by such examination and that it would have to be determined by the X-rays. This was done by Dr. Sweet and with great satisfaction I was able to do what I promised the patient. The eye was turned strongly toward the inner canthus and I passed a strong magnet in but failed to remove the metal because it was entirely encapsulated. I then passed a strabismus hook into the wound, picked up the mass of connective tissue and with a little effort brought it forward to the lips of the wound. I then passed the hook back and forth to see if I could detach this tissue, but failed. I then seized it with forceps and with the scissors cut it from its attachments, and upon removing it found the foreign body encased. When the mass was placed in the hand and a magnet approached it, it would move but could not of course adhere to it. One of my friends asked me when I concluded the operation, "Doctor, when will you remove the eye?" It did not seem to me necessary to do so, and a week later the eye was in good condition and now it is all right, though the pupil is blocked by a dense mass of connective tissue.

Dr. G. E. DE SCHWEINITZ of Philadelphia—Through the skill of my friend, Dr. Stern, I think I have saved at least one eye by the use of the X-rays. The details were localized without the excellent apparatus of Dr. Sweet which we did not have at hand at that time. It is now five months since the operation and the vision is 20-50.

THE ELECTROMAGNET OF HAAB IN THE REMOVAL OF PIECES OF STEEL FROM THE INTERIOR OF THE EYE.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN E. WEEKS, M.D.

NEW YORK, N. Y.

The introduction of the large magnet for the removal of pieces of steel or iron from the interior of the eye, which we owe to the enterprise of Prof. O. Haab of Zurich, provides us with an instrument of much value in a large proportion of such cases. It is of no value whatever in the cases where the foreign body in the interior of the eye is non-magnetic; fortunately such cases are not the most common.

Haab's interest in strong magnets for this purpose was engaged by the first case which he reports ("Trans. Oph. Soc.," Heidelberg, 1892, p. 162). The patient was a woman 32 years of age. On June 10, 1892, a piece of steel passed through the cornea and anterior chamber and lodged in the posterior part of the lens projecting into the vitreous. Haab thought that if he could bring the piece of steel into the anterior chamber its removal would be easy. Three weeks after the accident, the patient was placed so that the cornea approached the conical end of the soft iron core of a large electromagnet belonging to the physiologic laboratory in Zurich, and Haab was overjoyed to see the piece of steel retrace the path which it had made through the lens and lodge in the anterior chamber, from which place it was easily removed. The results obtained by the use of a large magnet in three cases caused Haab (*Beiträge z. Augenheilk.*, vol. xiii, p. 68) to have a special magnet made after designs suggested by Professor Kleiner in charge of the physical laboratory of the high school in Zurich. The dimensions are as follows:

Core of soft iron; diameter, 10 cm.; length, 66 cm.; weight, 30 kg.; beveled at the ends at an angle of

about 65 degrees to the perpendicular at the base of the cone. The point on either end is made to screw on so that more elongated and smaller points may be attached. Two spools of insulated copper wire are fitted to the core. These spools are separated from each other by an interval of 7 cm. The spools are composed of insulated copper wire 2 mm. in diameter which is wound in layers until the spool reaches the diameter of 23 cm. The spools are beveled at the ends corresponding to the core. The connection is made by means of the wire that enters each coil at its mesial aspect. The magnet is held in position by means of a brass stand to which it is pivoted, and the brass stand is attached to a suitable support. Haab's magnet, after which the one at the New York Eye and Ear Infirmary was constructed, employs a current of 50 to 60 volts and 6 to 8 amperes. The magnet will

placing the cornea against the point of the magnet, but not through the lens or iris. The larger the foreign body the greater is the attractive force exerted.

Haab's idea was not that the large powerful electromagnet would supplant the small electromagnet, but that in certain cases it would serve to remove the foreign body through the original wound; in some cases it would serve to bring the piece of iron or steel to a part of the eye where it could be easily removed by incision and use of the small magnet, and in still other cases it could be employed for diagnostic purposes. All of these procedures are valuable and can not be so readily accomplished by any other means.

The following cases, occurring in the author's practice are illustrative:

Case 1.—August S. (*Arch. of Oph.*, xxvi, p. 84) aged 15 years, came to my office May 3, 1896. About eighteen hours before, while playing with two hammers, striking one against the other, a bit of steel broke off and struck him in the left eye. The patient consulted Dr. Knapp, who kindly sent him to me with the request that a trial be made to remove the foreign body with the large electromagnet in possession of the New York Eye and Ear Infirmary.

Status præsens.—A small curved wound 2.5 millimeters in length, from which a bead of vitreous and a piece of iris protrudes, is observed at the limbus conjunctivæ to the inner margin of the cornea and on the horizontal meridian of the globe. The anterior chamber is partly filled with blood. Pupil oval and drawn to the nasal side; it measures 5 by 8.5 millimeters. There is some blood in the vitreous chamber. Tension —2. Vision = perception of light. The patient was immediately sent to the Eye and Ear Infirmary, admitted on my service and prepared for operation. Dr. Knapp and many others were present at the operation. Under cocaine anesthesia, the prolapsing iris and vitreous were excised. The wound was then enlarged by continuing the incisions in the limbus above and below, 2 millimeters at each end, and by making an incision 2 millimeters long into the corneal tissue at right angles with the vertical incision; the whole forming a T-shaped wound. The patient was then approached to the sterilized point of the great magnet, and when the eye was within about 4 millimeters from the conical end of the magnet, the piece of steel flew from the wound in the eyeball and adhered to the point of the magnet. The pillars of the coloboma were replaced, the margins of the wound adjusted, atropin instilled and a double bandage applied. The piece of steel measured 2.5 millimeters by 1.5 millimeters by 0.75 millimeter.

Seven days after the operation the patient left the hospital, the wound had healed and the blood had disappeared from the anterior chamber. The vitreous was hazy and remnants of a clot were present in the inner third of the vitreous chamber. There had been no pain and no inflammatory reaction after the operation. Seven months after the accident the vision with correction equaled 20-30 +, the lens was perfectly transparent and the eye was used with its fellow without discomfort.

In this case, the piece of steel pierced the fibrous coat at the limbus, passed through the iris and suspensory ligament and lodged in the vitreous humor, not injuring the lens. The result proved the wisdom of the attempt to remove the foreign body through the original wound.

Case 2.—Henry W., aged 18 years, Feb. 27, 1896. Two hours before presenting himself at the New York Eye and Ear Infirmary, while at work punching bolt holes in steel plates, a small piece flew and struck him in the right eye. He was immediately admitted to the Infirmary on my service.

Status præsens.—A small penetrating wound about 3 mm. in length was observed in the limbus at the lower margin of the cornea. Slight hyphemia; anterior chamber one-half the normal depth; pupil drawn slightly downward. A small black spot was observed in the sinus of the anterior chamber below, which was supposed to be the foreign body.

Operation.—Cocain was instilled and the tip of the small electromagnet was applied to the lips of the wound without result. The wound was then slightly enlarged with scissors and the small magnet again applied without result. The

Electromagnet. Pulling in straight line from point of tip, 6 pounds. Pulling with two pieces on steel placed on side of cone, 15 pounds. Pulling with piece of steel placed endwise on base, 7 pounds.

carry a current of 20 to 30 amperes for a short time.

Strength of the magnet.—Attraction for 1 gram of iron placed 5 mm. from the point of the magnet, 5.6 amperes, 113 grams; 7.9 amperes, 213 grams. Distance 10 mm., 5.4 amperes, 24 grams; 8.2 amperes, 63 grams; 10 amperes, 93 grams. Distance 15 mm., 6.4 amperes, 18 grams; 10.5 amperes, 63 grams.

A glance at these figures will suffice to acquaint one with the rapid increase in the power of the magnet with an increase of the tension of the current, also the rapid decrease of the attractive force on increasing the distance from the magnet.

By experiments Haab found that a piece of iron weighing 0.02 grams, lodged in the posterior part of the vitreous chamber could be made to pass through the vitreous and zonula and to engage in the iris by

patient was then brought to the large magnet and the eye at the site of the wound made to approach the point of the magnet in a right line. Pain was experienced and the tissues at the site of the wound bulged markedly. The wound was again slightly enlarged and a second attempt made to extract with the large magnet. The foreign body did not escape but it became evident that the foreign body was immediately behind the iris, which was drawn forcibly against the wound. A small iridectomy downward was done and the eye again approached to the magnet. No result. The wound was then converted into a T-shaped one, the eye approached to the point of the magnet and when within 2 mm. of the point the foreign body flew from the eye and became attached to the point of the magnet. The columns of the coloboma and lips of the wound were carefully adjusted and a double bandage applied. The piece of steel was 4 mm. long and 1.5 mm. in diameter; it had undoubtedly passed through the cornea, iris, zonula at margin of lens and lodged in the vitreous chamber.

Five days later, eye quiet, numerous floating opacities in vitreous from previous hemorrhage, obscuring details of fundus. Lens clear. March 12, discharged. Eye quiet. V. = 2/200. May 1, 1897, lens partly opaque, anterior chamber shallow. V. = 1/8. Eye very slightly injected but painless.

Case 3.—Delare M., aged 41 years. Dec. 18, 1896. This morning while at work as a boiler riveter, he was struck in the eye by a piece of iron, presumably from a rivet. The patient was admitted to the New York Eye and Ear Infirmary on the service of Dr. H. D. Noyes, who kindly permitted me to conduct the case.

Status præsens.—Marginal wound of lower lid 6 mm. long, corresponding wound of cornea, linear and extending 6 mm. into clear cornea from the limbus upward and inward, 30 degrees from the vertical meridian. The wound also extends an equal distance downward and outward from the limbus, dividing the sclera and conjunctiva. Anterior chamber partly restored. Small quantity of blood on iris below. Iris apparently uninjured but adherent to posterior lips of corneal wound. Conjunctiva at site of wound swollen and ecchymosed. Fundus can not be seen. V. = 1/∞. Projection normal.

Operation.—Cocain anesthesia. The eye was approached to the point of the large magnet. Pain was complained of and there was a possible bulging of the tissues at the site of the wound. The wound was enlarged downward and a T-shaped incision made. Repeated attempts were made to remove the foreign body by bringing the point of the magnet into the wound. Pain was complained of, the eyeball was forcibly drawn onto the magnet and rotated slightly inward, but the foreign body was not removed. The patient was then etherized and the small magnet employed; the probe point being passed to the posterior part of the eye. Although at one point traction was experienced and it was thought that a metallic substance was felt, there was nothing more positive and no foreign body could be removed. As the patient had not consented to removal of the eye, the scleral wound was sutured and the eye bandaged. December 22, more or less pain has been experienced since the operation. Chemosis marked. The patient consented to enucleation, which was then done. On introducing the scissors to divide the nerve the foreign body was felt lying close to the sclera. Examination of the globe disclosed a linear wound situated a little to the temporal side of the optic nerve through which the chip of iron had almost entirely passed. Its force was spent just as it emerged from the sclera against which it lay, being displaced by the point of the enucleation scissors. The foreign body proved to be a piece of iron, irregularly circular, measuring 6.5 mm. in diameter by 1 mm. thick. Recovery was uneventful.

The magnet has been used by some of the surgeons of the New York Eye and Ear Infirmary for diagnostic purposes and found to be of considerable value in determining the presence of a piece of steel in some part of the globe.

My experience in the use of the large magnet has forced me to recognize its superiority over the small magnet in all cases of recent injury where the wound is situated in the anterior segment of the globe where it can be approached by the tip of the magnet in a right line. With slight enlargement of the original wound, the foreign body, if it be steel or iron, can be made to retrace the path made by it and the removal effected without introducing an instrument into the interior of the eye and without making a second opening into another part of the eye.

We all know how seldom an eye recovers with any degree of vision and how often it becomes necessary to remove an eye after a foreign body has been extracted by the usual opening through the sclerotic employing the small magnet. I think that the use of the large magnet will give us a large percentage of recoveries. In cases where the foreign body has passed into the vitreous and remained for more than a week, I doubt the value of the large magnet, but in cases where the lens is the resting place of the foreign body as in Haab's first case, it will be of value. For diagnostic purposes it will aid materially.

DISCUSSION.

Dr. HAROLD GIFFORD of Omaha—Some years ago I had one of these Haab's magnets made. I am afraid that members of the profession have been frightened away by the idea that they were very expensive. I do not know whether I have a liberal electrician or not, but I had the magnet made for about \$72. The only difficulty I find is that it is hard to keep at hand a source of electricity that will run it. I at first had large storage batteries made, but when I wanted to use them they had usually run out. The ordinary alternating current will not suffice and it is hard to get connection with the street current. This magnet is certainly a great instrument and these cases of Dr. Weeks illustrate its value, though I should not be inclined to limit the use of the magnet to recent cases nor to cases in which the foreign body is in the anterior portion of the eye, it is certainly worth while trying for deeper objects. I never yet have brought out a foreign body with the Haab magnet I am sorry to say, but it has given me useful indications as to what I should do. In one case I was not sure whether the foreign body was in the vitreous, in the sclera, or had passed through the eye. The Haab magnet showed me that it was just behind the iris. I went into the wound then with the small magnet and although I never knew whether I got it out or not, the man's symptoms immediately ceased. In another case where the lens matter was cataractous immediately after the accident, I used the large magnet, and as the man had no pain, I judged that the substance must either be fixed in the sclera or had gone through. I waited, the lens cleared up; it had been so opaque at first that I could scarcely see any of the fundus, and at the end of a few days I could see perfectly well and found the foreign body embedded in the sclera.

Dr. H. KNAPP of New York—I think it is of very great use especially if it is not necessary to go into the vitreous. To go into the vitreous, even if you get the body out successfully, and find that the eye is good for three or four months, it will not be good after three or four years; so if you can get it out without going into the vitreous this instrument is of immense value.

Dr. J. A. LIPPINCOTT of Pittsburg—The disadvantage of the Haab magnet is its non portability. If a magnet can be constructed that is portable, it can be used where this is not serviceable. Some few years ago I had such a one constructed; it would hold up about fourteen or fifteen pounds from its point, which is considerable force. With that I have removed five foreign bodies from various portions of the eye, by using a current from the street, or rather, by continuous current from a private establishment. These large magnets are also of great value in a diagnostic way, for they not only demonstrate the foreign body in the eye by means of the pain elicited, but you can demonstrate the approximate position of the body. In all the cases in which I have operated I was able to tell about the place occupied by the foreign body by eliciting pain and traversing that area in gradually diminishing circles, with a small needle attached to the magnet.

Dr. S. C. AYRES of Cincinnati—I have never used the Haab magnet but have had a large experience with others. The first time I used it I was very successful and the patient was saved very fair vision. In another case where the foreign body, a crescent shaped piece of steel, had penetrated the cornea, I passed the magnet in and could feel that it came in contact with a foreign body, but the sensation was so slight that I was somewhat uncertain. I found later, after enucleation, that the foreign body had penetrated the sclera and my magnet had come in contact with the end which was protruding in the vitreous. In another case I found the foreign body encysted and in another discovered it later in the orbit.

Dr. E. E. HOLT of Portland, Me.—Having had quite an experience with the use of electromagnets, I have felt quite interested in this subject. I have found that in those cases in which I could make out the exact location of the body it was

quite as difficult to get the body out, or more so than if I could only estimate where it was. I think in 75 per cent. of my cases I was unable to see the body, but only estimated its position and in most of those cases I succeeded in getting the foreign body by the magnet.

Dr. J. E. WEEKS of New York—I wish to correct the impression that Dr. Gifford obtained, that I limited the use of the magnet to detecting pieces of steel in the anterior portion of the globe. Experiments made by Haab show that pieces of steel that are encysted will not be affected in the majority of cases except that the contact causes some pain to the patient and as a diagnostic means the magnet serves a good purpose.

The magnet is not portable and consequently is limited somewhat in its usefulness. A case I had a few days ago illustrates this very well. It was necessary to open the sclerotic near the equator of the globe and it was impossible to move the patient to the Haab magnet after this opening was made, because of the fear of producing prolapse of the vitreous humor. In that case the small magnet was used with success.

SHOT-GRAIN WOUNDS OF THE EYE.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

RY LEWIS H. TAYLOR, M.D.

WILKES-BARRE, PA.

It has been my fortune or misfortune to have under my care from time to time, a large number of patients suffering with wounds of the eyeball. Some of these have proven especially interesting to me owing to the serious nature of the injuries and the final results attained by conservative treatment. From among them I desire to present to the Section the histories of a few cases of shot-grain wounds, which I will relate briefly and follow with such remarks on wounds of this character as this brief paper will allow.

Case 1.—E. G., aged 37 years, came in the evening of Nov. 22, 1892, his right eye having been struck about 3 o'clock in the afternoon, by a shot grain from a companion's gun. From his position at the time of the accident the shot had evidently first struck a stone wall and then glanced to the patient's eye. It had passed through the lower lid and entered the globe just inside of the sclerocorneal junction, the iris being partly caught in the wound. The shot could not be seen so I instilled atropia and decided to wait till morning.

On the morning of November 23, the iris being dilated the shot grain could be seen imbedded in the lens and I decided to attempt its removal.

After making a downward section and iridectomy, with combined external and internal manipulation with loop and spatula, I succeeded in dislodging the grain and then removed it with forceps. The eye was bandaged and treated with atropia and boracic acid daily. The reaction was considerable, but this quieted down finally and the lens absorbed leaving a fairly good eye in appearance but with a dense capsule remaining and no useful vision.

In July following (1893) I lacerated this membrane with dissection knife, leaving a clear central pupil with vision, in 1895, of 20-c.

Case 2.—G. C., aged 27 years, was out hunting on Nov. 2, 1894, and a stray shot from his companion's gun struck his left eye penetrating the upper lid and entering the eyeball a quarter of an inch above the corneal scleral junction. He entered the Wilkes-Barre Hospital on November 3, and I treated him there until November 24. When I first saw him the anterior chamber was full of blood, iris invisible, and vision entirely gone. The patient was placed in bed, atropia instilled and leeches applied to the temple from time to time. He came to my office November 28, with iris entirely clear, pupil dilated V. 20-cc and fundus partly seen with the ophthalmoscope.

Dec. 24, 1894. Eye now free from irritation and looking well. Pupil still dilated. Ophthalmoscope shows a dark object in the anterior part of the vitreous resting on the floor of the eye, probably the shot grain encapsulated. V. 20 c. The nerve can be partly seen with the ophthalmoscope. Some shreds remain in the anterior part of the eye. Now use acid boric, with weak eserin solution.

Feb. 27, 1895. V. in O. S. 20-lxx, some in 20-l. Nerve and vessels quite distinct. Shot still remains in the anterior part of the vitreous back of the lens. With +1, V. = 20-xl.

March 30, 1895. V. = 20-xl with +.50, 20 xxx. Doing well,

no pain or inconvenience. There is a slight depression in sclera at the point where the shot entered. In this case, with treatment wholly conservative, the patient recovered with useful vision and saved his eye, which at first appearance decidedly indicated enucleation.

Case 3.—J. T., aged 27 years, came Oct. 26, 1896. He was out gunning the previous afternoon and was shot in the left eye. One grain entered the eyeball a little above and back of the insertion of the internal rectus, but it could not be determined whether this lodged in the eyeball or passed entirely through it. Another shot penetrated the upper lid near the central margin, about three-eighths of an inch above, passed entirely through the lid and probably into the eye though the corneal wound could not be seen. Another passed through the right ear and another under the skin of the right temple for a half an inch.

The lids and conjunctiva were much swollen and blackened with extravasated blood. He was seen on the evening of October 25, the day of the accident, by Dr. Buckman, who instilled atropia and ordered iced compresses to be used through the night. There was now no pain, the pupil dilated, the conjunctiva much swollen but the eye quite comfortable. A clear view of the fundus could not be obtained. There was much cloudiness and evidently blood in the vitreous chamber. He could see a waving hand but could not count fingers at any distance. Here was a serious wound and one in which, owing to danger of subsequent sympathetic ophthalmia, enucleation would probably have been justified. In view of the good result in the previous cases I decided to delay operation and endeavor to save the eyeball even though a sightless one. No effort was made to find the shot. Iced compresses were continued and atropia instilled every three hours.

On October 28, the eye being entirely comfortable and swelling subsiding, the iced compresses were discontinued. Pupil was now dilated but not quite regularly so.

October 31, he reported that in the morning when he first comes to the light the right eye is sensitive, but it soon becomes accustomed to the light and is all right. Patient is not confined to the house but comes to the office daily and his eye is kept bandaged.

November 3. Clearing nicely. Sclera showing. A little blood in anterior chamber.

November 5. Now worse: he went, on the evening of November 3, to be initiated into a lodge and for the first time encountered a bright light. Both eyes congested. Atropia now used in both and iced compresses applied. This irritation soon subsided and the eye again did well, but on November 16, knowing the possibility of future complications, I advised a consultation and he went to New York, saw Dr. Knapp and remained two weeks under his care. Dr. Knapp agreed as to the possibility of saving his eye and advised delay as to operation, and keeping careful watch as to signs of sympathetic irritation, etc.

I kept him quiet for some weeks, using atropia occasionally. Early in January he went back to his work as mining engineer and reported in the latter part of January, 1897, that he was able to continue his work with the right eye all day without fatigue or inconvenience. There is still no vision in the injured eye, as he merely sees a waving hand. He is entirely comfortable and greatly pleased that the eye was not enucleated, though he was perfectly willing to have it done in the first place had I so advised, rather than run any risk whatever of injury to the other eye.

I saw him recently, May 23, 1897, and the eye was then doing well, V. 20-cc. He can read J. xvi, and the eye seems to be gaining daily. He first noticed that he could see some time last February when out surveying while there was snow on the ground. He is annoyed a little with diplopia, but this is lessening as time goes by.

While thinking of preparing a paper on this subject I have been interested in looking up the literature of similar cases. While not extensive it is certainly suggestive and well worthy the consideration of those who are so ready to enucleate every eye that sustains a serious injury.

Valois (quoted in *Annals of Ophthalmology*, January 1897, p. 193) asserts that, in his experience, shot are among the most frequent of the foreign bodies that by accident penetrate the eyeball; they may enter the globe directly from the gun, or indirectly, after having passed through, or glanced from some other foreign body. "Wounds received from direct

shot are less apt to give trouble than those received indirectly, because, in the latter instance, they may be infected from contact with the reflected body, or the shot may be flattened and so inflict an irregular wound, a condition of things that materially increases the chances for infection after the accident. It is not believed that shot produces the slightest inflammatory action by virtue of any chemic properties of lead; although the vitreous promptly resents the presence of all foreign bodies, it is to be remembered that a shot is tolerated much better than any other extraneous substance."

A very interesting case of gunshot wound of both eyes, studied nine years after the accident, is reported by Dr. Robt. R. Saunders in *Annals of Ophthalmology*, July 1895. In this case one eye recovered full vision while the sight of the other was entirely lost.

Dr. Badal (*Annals d'Oculistique*, January 1895) reports a case in which an eye enucleated on account of shot-grain wound showed upon examination that the shot had crossed the eye and passed out through the sclera of the opposite side and lodged in the orbit. This is the second time he had found a similar condition. He pertinently adds: "I am led to think that hereafter it will be best to wait and not enucleate an eye wounded under similar conditions, as the shot which is lodged in the orbit is in general very well borne and the eye preserves its form and gives no occasion for surgical interference." Dr. Lagrange in discussing the above says: "I have seen a patient with the same conditions as those described. A shot had penetrated the eye and I proposed enucleation, which was refused. Some time after I saw the patient again with the eye in very good condition. In the future I shall be more reserved and wait until enucleation is necessary." Dr. Simon Snell ("Transactions of the Oph. Soc. of the United Kingdom," 1893), reports a case in which a pellet of shot was driven through the eyeball, with retention of perfect sight. "The patient was seen the same day and the question of enucleation delayed to obtain consent of the lad's father. Atropin and iced pads were used. On the following day the eye was doing so well that the question of enucleation was delayed from day to day. The vitreous gradually became clear and it became evident that no foreign body was situated in the interior of the eyeball. It was moreover rendered probable that the pellet which had entered the eyeball through the sclerotic on the inner side had passed out again close to the optic disc on its inner side. Vision further improved within a few days after the accident, and gradually returned to practically normal sight. Nine months after the accident he reads J. 1 readily and V. = 6-6."

T. R. Meux ("Transactions of Tennessee State Medical Society," Nashville, 1896) reports his own case in which the shot entered the eye causing considerable reaction. Several surgeons advised enucleation, but the eye subsequently recovered so that eight and one-half years after, no difference could be distinguished between the two.

Playne ("Oph. Hospital Reports," London, 1858) reports a case in which shot entered the eye causing strabismus and ptosis with subsequent entire recovery.

Dr. Casey A. Wood (*Amer. Jour. Oph.*, 1890) speaking of the comparative danger from shot and other wounds of the eye, such as knife blade, glass, etc., says: "Less likely also is the shot to disturb the ocular membranes, to make a ragged wound, or to

remain in the cavity of the globe. It goes through and makes a 'clean' passage. In scleral ruptures and in penetrating wounds made by other agents, the probability of other accidents is also greater than when small shot enters the eye. Among these are dislocation of the lens, retinal detachments, loss of vitreous and extensive intra-ocular hemorrhages. In a word, so far as the eye is concerned, the effects of wounds made by small pistol bullets and the various kinds of bird or buckshot are confined to the tissues through which they immediately pass, while the lesions resulting from scleral ruptures and penetrating wounds of other kinds are far more reaching and destructive in character."

It has seemed to me that shot-grain wounds are really less dangerous than we would naturally expect them to be from the nature and severity of the injuries received, and that in some way these grains are more nearly aseptic than foreign bodies in general. I thought this might be due to the heat generated by the powder explosion, but on examination of an ordinary bird-shot shell I find, covering the powder, a series of wads at least three-fourths of an inch in thickness, so that it is not probable that any of the flame from the powder explosion comes in contact with the shot. The heat developed by the velocity of the shot in passing through the air is thought by many to render the grain aseptic, but Dr. Suter of Herkimer, N. Y., claims to have proven by experiment that the heat developed by bullets during the passage through the air is not sufficient to render them aseptic as is generally stated. He found at least that the bacillus of anthrax would survive the ordeal and infers that it is not safe to consider bullets sterile of the germs.

Tornatola reported (*Arch. für Augenh.*, 491) in twenty-one cases of shot-grain wounds of the eye that he had noticed sympathetic affection necessitating enucleation in only a single case. He attributes this favorable result to the antiseptic treatment of the wound. Shot-grains discharged from a gun were always found aseptic, while those taken in the condition as received from the store and placed in gelatin or bouillon always developed numerous colonies from which he could often isolate the staphylococcus pyogenes albus. In experimental shot-grain wounds in the eyes of rabbits in eight cases out of ten he retained the form and tension of the bulb, provided the eye was disinfected previous to the wounding and treated antiseptically immediately after. On the other hand, in twenty cases wounded in a similar manner, in which there was no attempt at disinfection and no treatment following the wound, there followed fourteen cases of phthisis bulbi, five of panophthalmitis and only a single case which retained its ordinary appearance."

I think we may safely conclude:

1. That shot grain wounds of the eye are less dangerous than wounds of similar severity from many other causes.

2. That in general an eye wounded by shot grains, unless the wound be one of unusual severity, should not be immediately enucleated, but should be treated conservatively under careful observation.

3. A patient with a wound of this character should rest in bed for a period of two weeks or more, and the wound be treated under most rigid antiseptic precautions.

Additional interesting cases bearing on this subject may be found as follows:

John Butler: London Med. Gaz., xiii, 1888.
 Arthur Benson: British Medical Journal, 1882, ii, 1085.
 J. W. Southworth: Buffalo Medical and Surgical Journal, 1872-3, xii, 9-10.

DISCUSSION.

Dr. C. W. KOLLOCK of Charleston, S. C.—I believe there are many eyes wounded by shot grain in which it is useless to enucleate because the shot has passed through the eye. In one case I saw, the shot passed directly through the ciliary body and then out into the orbit. I had the pleasure of examining this eye four or five years afterward and there was no trouble with the eye.

Another point in these cases is that those cases in which the shot passes through the cornea without wounding the lids, if they remain in the eye there is not apt to be any ecchymosis of the lids. If the shot has passed through into the orbit there will be. That I believe to be a diagnostic point.

Dr. C. A. WOOD of Chicago—Some years ago I reported a series of these cases in the *American Journal of Ophthalmology* and I came to nearly the same conclusions as Dr. Taylor has. I then advanced the idea that shot grains were probably aseptic at the time of penetrating the eyeball. It seemed to me the friction of the shot grains in passing through the air rendered them sufficiently aseptic to account for the condition that occurs after the trauma. I think that has much to do with the favorable results obtained after injuries of this sort.

Dr. ROBERT L. RANDOLPH of Baltimore—I think that Dr. Wood has suggested the probable explanation of this matter. Some few years ago Dr. La Garde of the U. S. Army made some experiments with regard to the infectiousness of gunshot wounds. He stood at varying distances from culture media and fired into the media with pistol and rifle. In the majority of cases he obtained negative results, that is to say the test showed that the bullet was aseptic. The aseptic condition of the bullet then would explain the comparative freedom from disastrous results after gunshot wounds.

Dr. HAROLD GIFFORD of Omaha—I would remind Dr. Randolph that the experiments referred to also gave a number of positive results and that the conditions surrounding the ordinary bird shot are not so favorable as those surrounding the bullet. You have not the chance of the flame and heat of explosion coming into contact with the shot as with the bullet in the smooth-bore rifle. The chemic properties are probably more important than the aseptic properties.

Dr. L. H. TAYLOR of Wilkes-Barre—I thought they were rendered aseptic by contact with the flame, but on examining the shells, I found them covered by a dense covering three fourths of an inch in thickness, so I conclude that the flame has little to do with it, but friction in passing through the air may have much to do with it.

IN WHAT CASES AND WHEN TO ENUCLEATE IN INJURIES OF THE EYE.

Presented in the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN M. FOSTER, M.D.

DENVER, COLO.

There is probably no class of cases that fall to our care that give us the same amount of anxiety and solicitude as to the probable and possible outcome, as that which occurs in the injuries, especially in the penetrating wounds, of the eye. The experience of years and a large number of cases does not enable us to say with any degree of precision, this case will have sympathetic ophthalmia, or panophthalmitis, or that that case will not. We know that in a certain class of accidents, especially in those where there has been deep, penetrating wounds, more particularly in the ciliary region, serious results are liable to follow, and they often do. But, on the other hand, how frequently we note the termination of these unfavorably appearing cases in kindly healing, without the slightest untoward symptom; no irritation of the fellow eye, and even a better result in the injured one than we had any expectation of seeing.

It is precisely this uncertainty, and the dreadful consequences that are liable to follow these injuries, that lends this subject an intense and continuous interest, giving it a respectful hearing at all times. If we could feel sure that any age, sex or condition gave an injured eye exemption from the liability of affecting its mate, we could have the comfort of feeling secure in at least a small percentage of our cases, but unfortunately we know of no such exemption. Our clinical experience has not given us such assurance, but, on the contrary, has shown beyond doubt that age, at least, has a bearing and not a favorable one; for we have ascertained that children under the age of puberty are more prone to sympathetic ophthalmia after injuries, than at any other period of life. We have not been able to go further, however, and determine any time at which there is any degree of immunity. The question is not the amount of safety age affords, but one that asks us at what age we feel the most anxiety.

Naturally, the first point of interest in any accident to the eye would be the character, and, secondly, the location of the injury or wound, affecting as they do our prognosis and treatment to such an extent, as is hardly the case in any other part of the body. Slight superficial injuries, such as are produced by blows with the fist or a dull instrument, causing contusions and bruising of the coverings and appendages of the eye without solution of continuity of the ball itself, while they frequently are productive of serious or fatal results to vision, are in the rarest of instances followed by sympathetic affection of the uninjured member. Indeed, so seldom do we find even a sympathetic irritation from this class of injuries that we content ourselves by bearing in mind the possibility of a complication, and concentrate our attention upon the alleviation and betterment of the injured eye. Under these circumstances, that is, with no pain, irritation or photophobia, we would hardly give the subject of enucleation serious consideration, bearing in mind also the large number of even severe injuries of the eye that are not followed by sympathetic ophthalmia; only two occurred in something like six hundred cases, thus allowing us to discard a large percentage of cases from the subject in hand.

It is a far different matter, however, when we deal with a penetrating or poisoned wound, even if the instrument or particle producing it is *not* left in the globe. Its presence, nevertheless, adds that much more to the gravity of the case; while a demonstration of its absence, which is not always an easy matter, does not give a sense of relief or a feeling of security. In any event, we have a serious condition before us, which is influenced by several factors, viz., depth, position and character of the wound, as well as the presence or absence of a foreign body. All serious questions, demanding serious consideration.

Our prognosis and method of procedure will be modified or entirely changed oftentimes by the position of the wound almost alone; that is to say, when we find a gaping, lacerated wound in the region of the ciliary process, we consider the case very much more serious and more likely to demand stringent proceedings than if it is in the conjunctiva somewhat remote from this situation. We can, I feel, be governed by the following: All things considered, a wound in the ciliary region more often demands enucleation than in any other locality, and that we should not hesitate in these special cases to do the operation if there is

excessive pain, indication of purulent inflammation in the affected eye, or if there is irritation, shyness of light, corneal haziness or discoloration of the iris, however slight, in the uninjured eye. The question of a foreign body in an eye renders the probability of an enucleation more probable, but is not *per se* an indication for the operation.

The question of a poisoned wound one with undoubted contamination with bacteria of any description, demands, as a rule, enucleation. I do not suggest this with the belief in my mind of the migratory theory of sympathetic ophthalmia; on the contrary, I am convinced that the only way for trouble to be started in the second eye is by means of the intimate relations between the lymph channels and spaces, the irides, etc., as shown by the majority of cases exhibiting a serous uveitis, punctate keratitis, which confirms me in the belief that a sympathetic ophthalmitis does not arise from a migration of bacteria through the optic nerve. In sympathetic ophthalmia, staphylococci and streptococci are occasionally found in both eyes, but are not the specific cause of the disease, as shown by our inability to reproduce it by inoculation. It is caused more probably by the irritation of the ciliary nerves producing a reflected disturbance of the blood and nutrition of the uninjured eye.

In panophthalmitis, microbes are plentiful, as one would naturally suppose. Streptococci, staphylococci, and varieties of micrococci, with marked infiltrations of the ciliary body and edema of the papilla.

However, it is not the purpose of this paper to discuss the merits of the different theories of the origin of the trouble; my own belief in the matter is expressed to explain in a measure my position as to the best methods of dealing with or against the disease, finding, as I have done, that section of the nerve does not replace enucleation as a preventive measure against sympathetic ophthalmia.

We must bear in mind that this disease is a rare one, and as our operations are mostly done as a prophylactic measure against its onset, or done in cases that have been blind for months or years, it renders our statistics inexact, especially as a sympathetic ophthalmia occasionally sets up after an enucleation has already been done. In this connection I will say that experience has proven that in these cases the inflammation is less virulent than that which occurs when the operation has been too long delayed.

In what cases to enucleate.—Give the operation serious thought in penetrating wounds of the ciliary region, but do not do an operation for every ciliary wound. Enucleate regardless of the situation of the wound in cases where there is marked inflammation of the injured eye and photophobia in the other; also when panophthalmitis is threatened.

The time to enucleate is as soon as possible after deciding it is necessary.

It is seldom that a prophylactic enucleation is followed by a sympathetic ophthalmitis; on the other hand, cures are at times established in cases where the symptoms have been well marked for several weeks. As a rule, however, in case the trouble has commenced, the primarily affected eye should only be removed after the inflammation has been so severe and lasted so long that there can be no hope of restoring vision. If sympathetic ophthalmitis affects the sound eye shortly after an enucleation of the injured, we feel certain that ill-defined and veiled symptoms

have been overlooked and it had already begun to suffer before the operation was performed.

Where the inflammation follows after long delay, how can we account for it? As an example note an atrophic globe following an old injury, absolutely quiescent for years, when suddenly an inflammatory action commences, and the fellow eye is lost with sympathetic trouble.

In panophthalmitis an early enucleation should be done for fear of meningitis following. This dreadful sequel has commenced as late as the twentieth day, but generally begins much earlier. We all know and recognize the deformity resulting from the lack of development of the orbit in a child, following enucleation, but this should not deter us from the operation in all suitable cases, for we must feel some pangs of conscience if sympathetic ophthalmitis occurs in a case that we have not operated on for cosmetic reasons. I am strongly inclined to lean toward the operative side when my first examination, shortly after the accident, leads me to feel positive that no sight will be regained in the eye.

WHEN EVISCERATION IS PREFERABLE TO ENUCLEATION.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. C. DUNLAVY, M.D.

SIoux CITY, IOWA.

The services of an eye surgeon are so often demanded in cases of either recent or remote traumatism of the eyeball, as well as for many conditions resulting from disease of this organ, that some general rules of surgical procedure should be adopted for the guidance of those whose advantages for rational information have been necessarily more or less curtailed, and who for lack of proper knowledge are more liable to treat a patient in the generally recognized plan of the surgeons of his community, whether or not this plan is practiced or sanctioned by the better and more enlightened surgeons as being the more rational.

In general surgery we have amputating surgeons, and in eye surgery we have enucleating surgeons, both of whom are perfectly proper and indispensable, but, alas, either are liable to travel at too rapid a pace and leave death and maimed bodies with their baneful results to follow their respective practices along the generations to come.

The surgical procedure of enucleating, or the evisceration of an eyeball, is done for several purposes of more or less seriousness or importance, for a certain class of patients. One class of persons who can not afford to lose extra time from business or labor will often consent to the sacrifice of an eye, when the ball could have been saved entire by proper patience and careful treatment. Others who bear pain poorly, will yield rather than undergo the suffering of a panophthalmitis; and finally, the skilful surgeon must demand the surgical means for purely scientific reasons to lessen the danger of the fellow eye. Until comparatively recently it has been almost a wholesale custom of surgeons, more especially those of less scientific attainments, to do the easier, quicker and more brilliant operation of enucleation in all cases calling for such interference, but a few well authenticated cases of death from meningitis following enucle-

ation during a high stage of inflammation, has aided very materially in calling a halt in this wholesale procedure, and adopting the more conservative and scientific operation of evisceration instead. The rule should be, if any can be established, in an injury to the eyeball, to eviscerate if the injury is of recent occurrence, say within a few days. The theory of this rule is based particularly on the supposition that the migration of septic germs has not yet begun. Whatever the theories of extension of inflammation to the meninges or causes of sympathetic ophthalmitis to the fellow eye, the more rational course to pursue is, for the surgeon to determine from all the conditions of the case, what appears best suited in each individual case. If his judgment be poor, the patient suffers.

It is perfectly rational in this condition, as in all others, to sacrifice as little as possible concurrent with the pathologic state of the eye. I believe no eye surgeon of respectability at the present time would think of enucleating when the globe is filled with pus, for the reason that channels already closed in the optic nerve against migrating septic bodies might, by severing the optic nerve, be opened up and admit the very sources of infection against which nature had fully guarded. And in cases where a foreign body has penetrated the eyeball and resulted in panophthalmitis, and where the foreign body can not be found by evisceration, it is better to enucleate and take the chances of meningitis, but as a rule, avoid everything possible of a traumatic character in either procedure.

In such cases, whatever may have been the cause, the rational procedure is to excise the anterior portion of the globe. The incision should be made far enough back that the iris and ciliary body should be included in that portion of the globe excised; then with a pledget of absorbent cotton dipped into a solution of sublimate, 1 to 2,000, or formol, 1 to 1,000, thoroughly wipe out all contents of the globe, leaving nothing except a clean and thoroughly washed sclera. This takes time and pains, but it is so rational that it well pays for the trouble. After the globe is thus thoroughly eviscerated and cleaned, a single stitch of No. 3 thread through the conjunctiva, not the sclera, drawn so as to merely shape the outer extremity of the sclera and not close the door completely, and an antiseptic pad of cotton or gauze applied under a light roller completes the operation; after-treatment on the usual plans; this for an eye filled with pus.

In a more recent inflammation, where the eyeball and orbital tissues are very much swollen and a destructive inflammation from some dirty or septic substance having penetrated the interior of the globe, the danger of meningitis is, to my mind, very great, and augmented by any procedure which will in any way tend to irritate the distal extremity of the optic nerve. An eye in this condition should never be enucleated. Eviscerate in practically the same manner as above described, except that the contents of the globe, which are not now purulent, can not be so easily and thoroughly removed by wiping and will need to be removed by the use of some small instrument, such as a scoop, spoon or spatula, introduced between the sclera and what is left of the uveal tract, and the contents in this manner carefully removed. The after-treatment as well as the operation is to be done under strict germicidal rules.

These two pathologic conditions will serve to illus-

trate the forms of panophthalmitis where evisceration and not enucleation should be done. In cases where the injury has been of such a nature as to leave cicatrices, which prevent the proper application of an artificial eye or to make the sunken globe appear more unsightly, or a constant dragging or pulling on the orbital tissues, which of itself may excite sympathetic ophthalmia, and from the nature of the injury these conditions are to be expected, the eye should be enucleated. In case of old inflammation, of whatever character, where the ball is tender, sore or subject to subacute attacks, if any part is left remaining the fellow eye is in constant danger and should be protected by the enucleation of the offending eye. In all cases where a foreign body is known to be lodged in the eye and there is greater or less inflammation, if the foreign body is not found by the process of incision or excision of the ball at some point, enucleation should be done.

At least two conditions exist where an eye should not be enucleated: When the globe is filled with pus and during a high state of acute inflammation.

604 Fourth Street.

DISCUSSION.

Dr. H. V. WÜRDEMANN of Milwaukee—I rise for the purpose of advocating in the majority of cases a properly applied enucleation. If the operation is completed by sewing up the conjunctiva in the form of a pouch we can get immediate healing and a stump that is partly movable, and if you wish to make the operation a little better you can pick up the recti muscles and bring them out of the wound. The patient can be fitted with an artificial eye within four days to a week afterward. Whoever has had a run of enucleation cases and gone to evisceration and had one case or more of sympathetic irritation will be apt to return to enucleation; whoever has done a number of successful eviscerations and has had one case of meningitis following his enucleation is apt to become a more earnest advocate of evisceration. Eight years ago I brought over a number of glass balls and I may have been unfortunate in having made a failure of the first two cases I operated on. In one I had sympathetic irritation, and since then I have been afraid to return to evisceration. This is despite the paper of Dr. Dunlavy and those of Dr. Fox. I have with me some specimens which I think show the advisability of enucleation [passing specimens]. One of the cases was an enucleation during severe panophthalmitis and the eyeball had to be removed to obtain drainage; simple incision did not give relief to the pus in the orbit.

Dr. J. C. DUNLAVY—The cosmetic effect has been fully discussed and we will not take it into consideration. Purulent orbital cellulitis should not be considered with this surgical procedure at all, for evisceration could not be expected to evacuate pus in the orbit. Neither enucleation nor evisceration should be adopted by any person as the sole plan of procedure, because there are cases where every man ought to know that one is better than the other. The effort to save as much of the body as possible in the one instance and to lessen the danger of meningitis in the other are the two points I wished to bring out. About two years ago, during a session of the local society, a patient came in with a piece of metal in the eye. I removed it with the magnet and he had no trouble whatever. Some time afterward the patient hurt that same eye and I performed an evisceration, and on wiping out the cavity something caught on the cotton and I found it to be a splinter of metal. I mention it merely because it would be so unlooked for.

The Toxic Principle of Mushrooms.—The active principle of the *agaricus muscarius*, or fly mushroom, acts by paralysis of the nerve centers, causing death from the heart. There is no doubt that it is one of the most powerful of vegetable poisons. The antidote is the sulphate of atropin, hypodermatically administered at the earliest opportunity. This muscarin in the form of the nitrate or sulphate appears in the laboratory as a brown deliquescent mass, and has a recommendation as an antihydrotic with some virtue as a cure for diabetes insipidus. The eye symptoms in mushroom poisonings appear to be unrecorded.

THE MANAGEMENT OF CHILDREN WITH AN INHERITED TUBERCULAR DIATHESIS.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY JOSEPH WILLIAM STICKLER, M.D.

ORANGE, N. J.

There are diverse views concerning the so-called inherited tubercular diathesis; some even deny the existence of such a thing; others fully believe in it. Vogel is one of the latter. He regards heredity as an important etiologic factor in the production of infantile tuberculosis, because children born of parents affected with this disease develop it when exposed to bad hygienic surroundings. Baumgarten thinks there is a virus transmitted from parent to offspring. Bend is arrayed against him. Edward Squire of London from a study of 1,000 cases concludes that heredity accounts for 9 per cent. of cases among children born of phthisic parents, in excess of cases among children of non-phthisic parents. He therefore believes that heredity in these cases means simply a tendency to suffer from diseases, tuberculosis among others, which all children born of weakly parents have in common. Dr. Solomon Solis-Cohen says, "to make our conception of the disease sufficiently comprehensive, we must include other elements than the bacillus and the changes in cellular structure, or in chemic constitution of solids and fluids brought about by its activity. There is in the constitution of the individual, anterior to bacillary infection, something that determines the fact of infection and that largely determines, also, the course and character of the results of infection. We must not remain satisfied to cover our ignorance by naming this determining element 'susceptibility,' or negatively, 'lack of resisting power' to the bacillus; nor is it any advance to speak vaguely, whether figuratively or literally, of 'favorable soil' and 'good culture medium.' That condition which makes the human tissues a receptive 'soil,' a favorable 'culture medium' for the tubercle bacillus, that condition which of old was called 'diathesis' and now 'susceptibility' is itself a disease, a departure from the norm; and I believe it to be the most important element in the morbid complexus termed tuberculosis. It is the element requiring the greatest care in prophylaxis, the most intelligent and faithful treatment." J. Lewis Smith says that the tubercular diathesis may be inherited. "Hence, the well-known fact of tubercular families." If both parents are tubercular, the offspring almost necessarily becomes so. Without further consideration of this portion of the subject I shall assume that children born of tubercular parents are *apt* to develop tuberculosis. I shall also assume that with proper care and management, the inherited diathesis may remain latent or be entirely overcome.

To this end I shall call your attention to a few measures which, to me, seem to be of importance. The first thing to be done for an infant whose mother is tubercular, is to secure a healthy wet nurse. In most instances when this is done, the little one will gain new strength very speedily. A French mother would, in France, have her child suckle a goat if a good wet nurse could not be found. Weaning should be gradual, and not accomplished during the warm months. As long as the child does well at the breast

it is unwise to interfere. Should artificial food become a necessity, very great care should be observed in its selection and preparation, and in the care of nipples, spoons, forks, bottles, glasses, etc. Sometimes inunctions of cod-liver oil, cocoanut oil or some other suitable oil will be found useful. It is unquestionably true that a few drops of brandy or wine before nursing will help the nutritive processes. Cod-liver oil, plain or in the form of emulsion may be given with excellent results in many cases, as may the dry preparations of malt, beef juice, malted milk or peptenized beef tea. Just here it should be remembered that the alimentary canal is a channel through which tubercle bacilli may find their way into the infant's system. Food containing the bacilli will do no harm in a healthy stomach and intestines, but in the event of sickness, altered mucous membrane, or absence of acid, the infected food may do great harm; hence, care in this direction. If cow's milk be used, it should be thoroughly sterilized. Dr. J. Lewis Smith directs that it should be placed in a steamer and subjected for two hours, to a temperature of 190 to 200 F. The child should be warmly but lightly clothed. The chest and waist should not be restricted and the limbs ought to have free play. If there be a catarrhal inflammation of the nostrils or throat, a cap of suitable material may be worn. It is quite important that the bowels should receive their share of attention. If the evacuations do not occur as frequently as they ought to; or are inordinately hard and expelled with difficulty, a mild laxative, enema or suppository is indicated. Gastro-intestinal catarrh would suggest mercury with chalk; calomel; aromatic syrup of rhubarb; castor oil; bismuth and other appropriate remedies. Should the child become greatly prostrated and be in an inland town or city, and the weather hot I know of nothing that will revive and restore to health as quickly and surely as a stay of a few days or weeks at the seaside.

When indoors, in cold or chilly weather, the child should have properly heated, but well-ventilated apartments. Draughts should be avoided and the temperature of the room never allowed to get so low as to chill the body. On the other hand be careful lest the temperature reach too high a point. From 65 to 75 F. is a good temperature. If the child should develop bronchitis or any other inflammatory affection of the air-tubes or pulmonary tissues the air should be kept moist. During the night, avoid sudden changes of temperature occasioned by faulty management of the heating apparatus of the room or house and protect the child against sudden changes of temperature due to change of weather.

The tubercular mother should not sleep in the same room with her child. In the homes of the very poor, the separation of the mother and infant at night is sometimes a difficult matter to manage, as in some instances there is but one room for the two. In such a case insist on the use of the cradle, placed as far from the mother as will be consistent with the care and protection of the child. Water warm enough to be comfortable, should be used for bathing the little one during the cold months; while cold water may be advantageously employed in warm weather. The bath should be given daily, but not prolonged, and followed with a brisk rubbing. These children should be shielded from contagious diseases, but in the event of their contracting them, the most judicious efforts should be made to support the system till the return

to health. If the child has left its mother's breast, it should have highly nutritious and easily digested food, the character and quantity of which will be determined by the age and condition of the child.

"Avoid the depressing refinements and undue attention sometimes witnessed in city homes." Continuous city life is bad at best for these little ones. "All recognize the bright, neat little town child, quite a little fairy as it flits about, presenting a strong contrast to the typical solid country child; but the latter is full of health and strength, while the town child is delicate and fragile. Medically, these graceful and fascinating little personages are unsatisfactory. They are not all strumous, but they lean that way. They usually receive cruel treatment from those who least intend it. Bright, quick-witted and affectionate, these mites are constantly amused and entertained when they would be much better left alone.

"I well remember one, the child of a distinguished American; two able and highly intelligent women devoted themselves to it all day long. It had ducks and water fowl in its bath, with which it played while the process of ablution was going on; and pretty it looked with its painted toys. But it never got far on its journey in life." Thus spoke Dr. Fothergill.

Progressive loss of flesh and appetite with other indications of failing health point to the need of medical measures such as syrup of the iodid of iron, lactophosphate of lime, iron, arsenic and bitter tonics.

These children should reside in a healthful locality and spend much of their time in the open air. Samuel West of London, believes that the only requisite which every suitable climate possesses is that of admitting of the patient's being as much in the open air and sunlight as possible.

"Whenever sufferers can spend all day out-of-doors, and when indoors can still live in a pure atmosphere, they will do well." I think, however, it should be remembered that no climate is proof against the dangerous emanations of a filthy soil, either in city or country. For this reason, if one be in search of the best possible climate for children predisposed to consumption, villages with populations of a thousand or more should be avoided. If the child must be kept in the village or city, as is often the case, great care must be observed in getting pure water and in correcting bad sanitary conditions in and around the house. I remember being called to see a patient (tubercular) under whose window was an open privy vault. The house had defective plumbing, and stood in a swamp. Such a combination of objectionable conditions must, as a matter of course, be unhealthful and should be shunned, no matter how good the climate of that particular part of country. It is interesting just here to note that Migneco, by a series of experiments, determined the exactness of Koch's statement that sunlight kills the tubercle bacillus in a short time. Bacilli, after ten or fifteen hours' exposure, cause only local tuberculosis; while after twenty-four or thirty hours; they cause no symptoms as a rule. In certain cases the bacilli will remain active, but will be attenuated in virulence. From these facts we argue that the free admission of sunlight into houses in which children with a tubercular diathesis live, will do much to aid nature in her effort to carry them through to a healthy manhood and womanhood. Dry cold air, if the child be warmly dressed, will do it good rather than harm. Strong winds, warm or cold damp air, and a foggy atmosphere avoid. As

soon as the child is old enough, proper breathing, with chest gymnastics may be practiced with great benefit. Dr. G. R. Butler recommends certain movements (*N. Y. Med. Journal*, Oct. 20, 1894), all of which are simple and easily accomplished.

Exercise A. First movement: Flex and rotate arms, fingers to shoulder, elbows at side. Second movement: Extend arms to side, palms down. Third movement: Flex and rotate arms, fingers to shoulder, elbows at side. Fourth movement: Hands down and back, extend palms midway.

Exercise B. Inhale, hold breath, revolve right arm twice slowly; exhale.

Exercise C. Arms extended to side and back, palms up. Grind shoulder blades, moving hands in small circles.

Exercise D. First movement: Extend arms at side, palms up. Second movement: Palms together in front of body. Shoulders high. Third movement: Rise on toes, inhale; extend arms to side and back as far as possible.

Exercise E. First movement: Extend arms to side, palms up. Second movement: Arms up touching fingers on top of head. Third movement: Clap hands over head, full length up. Fourth movement: Arms down at side.

I believe great benefit accrues from forcible inflation of the lungs, holding of the breath and a slow expiratory movement, the air escaping gradually through the nostrils. By this process the air vesicles, especially those of the apices, are well distended; an increased amount of oxygen is introduced into the blood and the heart is strengthened in its action. These are some of the measures which seem worth the trying if we would prolong the lives of the individuals under discussion, and it is certain that these lives are worth the effort. That many of the number develop tuberculosis and die in consequence of it, the statements of Lorey and Biedert prove. The former gives the ages of 162 tubercular cases among children as follows: From the first to the third month, 1; from the third to the ninth, 11; from the ninth to the twelfth, 31; between the first and second year, 55; from the second to the fourth, 41; from the fourth to the twelfth, 23. The latter says that 6.8 per cent. were observed under 1 year of age: 48 from the first to the fifth: 27 from the fifth to the tenth, and 18 per cent. from the tenth to the fourteenth year. Thus it is seen that tuberculosis is quite frequent between the ages of 2 and 4 years. I have said nothing about serum therapy in this connection because it seems to me that results thus far obtained do not justify its employment. If it could be shown that an anti-tubercular serum has the property of setting into action the processes which protect the economy against the development of the disease then it would seem wise to use it. But of that we can not yet be certain. What the individual with a tubercular diathesis wants is a reinforcing of the tissues; an increased resisting power in each cell; an uplift of the vital powers; the very best life force conceivable. This is to be gained, perhaps with the greatest certainty, by attention to the suggestions already made.

I think any paper on this subject would be incomplete without reference to the intellectual training of the child, a matter concerning which both parents and physicians have very different opinions. While in the South last winter I heard two mothers discuss this question, and as their views bear directly upon

the question before us I quote what they said. Mother number one said her child was well advanced in her studies and very fond of going to school. Mother number two said: "Is that your child at the far end of the piazza; that little tot about 6 years old?" "Yes." "Well, doesn't she look pale and tired? Seems to me I would worry if she were my child." "Oh, well, I know she is weak and apt to develop lung trouble, but of course she must know something; how dreadful to grow up and be behind other children in her studies." "Well, we tried your plan for a time with our little daughter, but she soon ran down in health, so we took her out of school and have kept her as much as possible in the open air. For the last few winters we have brought her to Florida to escape the sudden severe changes and cold winds of our northern home. Here, she is out of doors all day when the weather is fine and she shows the benefit of this new life. Look at her and see how rosy and vivacious she is." "Yes, that is true, but when will she learn anything?" "When she is older and strong enough to endure the strain and confinement. What we want is to have our daughter live and enjoy good health." "Well, do you know I really think you're about right. Maybe our child would not be so frail if we had adopted a different course. The truth is we were compelled to leave our home and come South on account of her failing health. We are quite anxious about her."

Is there not a lesson to be learned from this little dialogue? Is it not manifest that the child with a tubercular diathesis will do better if allowed to exercise freely in the open air than if shut up several consecutive hours daily in a room, bending over a desk, breathing vitiated air and having its delicate organization unduly taxed? What is to be gained by developing the intellect at the expense of health? Suppose the child does not learn much from books during the first few years of life? There will be time enough later, if the health be carefully looked after, for the acquisition of knowledge. As a rule, these children are precocious and are disinclined to enter into the wholesome and active sports of which their healthy little friends are naturally so fond. Hence the more urgent the necessity of insisting upon plenty of exercise and life in the open air. In many instances a few simple lessons may be taught each day but beware of overdoing in this direction. There are other details of management which will present themselves to your mind as a remedy for this state of affairs, but I trust I may sufficiently emphasize the importance of doing more than has been, or is being, done for a large number of children whose inheritance makes them liable to the development of one of the worst diseases we have to deal with, one which destroys one-seventh of mankind. Is it not possible that we may err in not considering as worthy of our special and thoughtful care the individual who does not present active positive symptoms of disease? Are we not prone to turn such an one aside with a few indifferent remarks about the necessity of taking care of the "general health"? In some instances do we not assume that parents will, in some way, take care of these little people; although we know them to be but poorly instructed, at best, as to what ought to be done. Perhaps I am more urgent in this matter than some of my professional friends; if I am, it is because some sad cases, cases badly neglected in early childhood, have come under my observation. Just recently a young man came to me with disseminated pulmonary

tuberculosis. Notwithstanding his early tubercular diathesis, he was allowed to remain in a climate calculated to enervate rather than to energize his feeble constitution. No particular attention was paid to his diet. He was allowed to run about, poorly protected, in rainy and cold weather as well as during the warm and dry periods. When he had a cold he was given a cough mixture and allowed to recover as best he might. If he complained of chest pains or a feeling of lassitude, he was ignored or told they were "growing pains" and laziness. When he complained of poor food or could eat but little of good food he was told he was "finicky." When he became old enough to help support the family he was put to work where the surroundings were unhygienic, hours long and the trade wearisome. Being obliged to go to the factory in all kinds of weather, he soon caught cold. His cough became troublesome and to make matters worse he got the grip. His lungs being his weak point he rapidly developed all the signs and symptoms of tubercular phthisis, so that at the present moment he is about hopeless, as I am, concerning his ultimate recovery. As he sat in my office dejected, poor, alone in the world and too weak to earn a few dollars with which to pay his board bills, when I was told that unless some generous friend should give him a little money he would not know where to find rest for his weary and diseased body; when I thought of how comparatively easy it would probably have been to have prevented such a state of affairs by careful and early attention to his physical condition; when I thought, in connection with his case, of many others I know of I was deeply moved and convinced of the wisdom of speaking, in conjunction with others, in behalf of this vast multitude of unfortunates who, without timely aid, must, many of them, drift into just such a condition of helpless physical wreckage as is now his portion.

DISCUSSION.

* Dr. W. S. CHRISTOPHER of Chicago—I heard enough of the paper to get the drift only, and I would like to hear somebody first discuss it who is opposed to it, because I happen to favor the Doctor's side in toto. The subject is one that is part of a broader matter than the relation of tuberculosis; it involves the relation of the environment to the child. Many factors the Doctor has brought out relating to the damage of the child by tuberculosis that are certainly causative factors, that assist in developing tuberculosis, that are equally potent in the development of other diseases. The reason for the existence of this Section, the reason for the study of pediatrics at all, as dissociated from other branches of medicine, is the necessity of reaching all the factors that go to make out of a puny child the strongest possible development. It is the function of the pediatrician not to cure measles or handle whooping cough, or give pills and powders, but to make out of a given child the strongest possible development; to first take into consideration all those factors of heredity which may, if allowed to accumulate, damage it, and then by so adjusting the environment, diminish the potency or effect of these factors as far as possible. With reference to the child with tuberculous ancestors, it becomes a question of building up the tissues with that form of food which experience shall in the future show to be the best, possibly along the lines that we now think the future may show. But when we get a history of heredity, it should never be expressed as "negative." There is no such thing as a negative family history. The family history is as much a part and parcel of the diagnosis of tuberculosis in childhood as is the demonstration of the micro-organism. The family history may show that the mother is tuberculous, or gouty, or that the mother is neurotic or possesses one of the types of mind and body that may be transmitted to the child, but the family history is never negative. We might as well say the child is sick, but no detail is necessary. It brings up the broad subject as to the influence of heredity as a factor of diagnosis. It also forces us to face the second element in diagnosis, that is the element in nutrition, which includes not alone the question of

how much food the child has had, not alone the question of the quality of the food the child has had, but those deeper questions of the relation to each other of the different viscera of the body. If we have a child with a mammalian pair of kidneys and a reptilian type of liver, not by any means uncommon, we have such a maladjustment of organs that there is necessarily a clashing of functions. Such things are to be considered under the title of the nutritive disturbances. Having settled these questions, then we are prepared to take up the question of whether there is tuberculosis or other infection in the case. I agree with Dr. Stickler, that the infection which is most important, the one we must fight most commonly, is this one of tuberculosis, and the essayist is very well justified in taking for his subject the relation of tuberculosis, as he has done. What I heard of the paper did not bring out the elements of the relationship of tuberculosis especially and that is the reason I have gone over the subject more broadly.

Dr. J. A. LARRABEE of Louisville—The remarks of Dr. Christopher lead me to believe we are all sliding on one hill. It seems to me the Doctor might have given us something to take exception to, but as it is we all agree with him.

Now, as to the broad subject of pediatrics, which we as pediatricians understand, but which the general practitioner does not comprehend, Dr. Christopher has put in a nutshell the whole evolution of this Section. It can not be appreciated by those who are not brought in daily contact with children. We must have the soil as well as the seed. Seed will grow luxuriantly and produce well only in soil that is adapted to it. There is in each of us a weak spot; we are wounded just as Achilles was wounded. We are protected to just the extent our ancestors were protected. A man is thrown into this world, representing the forces behind him, just as a ball is thrown into the air and will go a distance proportionate to the force with which it was thrown. There is nothing so catching as longevity, and that is the reason the life insurance companies in the secret room pass or reject the applicant on that ground alone. You may have disease, gout or rheumatism, but if your parents have been octogenarians, it goes far for you. But a bridge is not stronger than the weakest point. To know the diathesis, the way my patients are traveling, is more important to me than knowing the acute disease. Knowing the road they are traveling, I believe the fortification is in building up the body. The Doctor's paper, in fact, bore up that statement; keep healthy and you will not be sick. The question is how to do this. It is known that whether the body craves or demands food makes no difference. The system of cramming or forcing food into the system is known. We all know how the goose is stuffed to make his liver good. The goose is not goose enough to eat all the time, and they have to stuff him just to make him grow fat. The goose, if he could would not do this, but he can not prevent getting fat when he is stuffed. So I believe in feeding, but above all, in sunlight and fresh air. Another point is the reinfection of tuberculous patients. These patients are born with barrel-shaped chests; they have a peculiar tubercular build. Those who are experienced in the study of diseases of children, can at once relegate the patient to his class. These barrel chested individuals need development. You must put them in an atmosphere that is free from tuberculosis. The cause of most of the deaths in tuberculosis is reinfection. We all have improvement in tuberculosis from a proper course of treatment, and under the microscope you can discern a lessening of the number of bacilli and you know you are doing the patient good. And any man who is gaining flesh is doing better, no matter what the microscope shows. But the patient becomes reinfected and down he goes again. Many parts of this country are becoming simply dumping grounds for these cases. Florida and southern Georgia for a time presented almost a sure cure for these cases, but now how is it? The germs are so thick there you can bottle them up and take them to Chicago and start an epidemic. The value of fresh air is emphasized by the fact the aborigines did not have tuberculosis.

Just in proportion as men live in cities, just in proportion as we congregate we will have consumption. The Indian did not have it. In the State prison in my own State, the Governor, who is a doctor, I am glad to say, took one look into the black hole and said, "This will not do; it can not be." Every human being put in there, in darkness and filth and bad surroundings, contracted disease, because the atmosphere was saturated with it. I expect we would smile at any one who would percuss the lower part of the lungs for incipient phthisis. We would say, "What are you doing there?" We always examine the apices of the lungs. Why? Simply because the upper part of the lungs has not been used. We are apt to store rubbish in attics, and nature does the same thing. We have about one-eighth of the people today suffering from residual air. The

upper part of their lungs, the part beneath the clavicle, is never inflated at all. I do not blame the Irish gentleman, Mike Robe, for getting his work in there. We do not breathe to the extent we ought to. It should be the rule of every individual at the end of the day to carry out the West Point rule, and with the heels and buttocks on a line against a wall, take twelve deep respirations before retiring.

I could not go further without simply endorsing what has been said. I thank you for having given this the trend it ought to have, and I hope this discussion will not stop with these erratic remarks.

Dr. HENRY E. TULEY of Louisville—This subject certainly is an important one, but I think the Doctor laid too little stress upon the importance of infection in children. I think Dr. Holt's statistics with reference to the postmortem findings in children would show us that the infection comes largely through the bronchial glands. In 99 per cent. I think the infection was noted to be in the bronchial glands. In many cases this was the only place where the infection was noted; in others, bacilli were found in other organs, but possibly they were only secondarily infected. So it would seem to me in the younger children the proper oxygenation of the blood and deep expansion of the lungs, would have little or no effect on the development of tuberculosis.

Another point, that probably more stress should have been laid upon, is how little effect we get from the placing of these children, with inherited diathesis, in hospitals, even when they have some concurrent disease. They develop the condition known as hospitalism quicker, possibly, than other children. The providing for them of open air roof gardens and sunning places, and open air porches where these children can stay, is certainly looking to the prevention of this condition of hospitalism. But even then they do badly in institutions, and if they are placed in hospitals with other diseases they should be kept there as short a time as possible. I think that is a condition that is not generally recognized.

Dr. Cook of Illinois—There were just one or two points slipped over in the discussion. In the matter of feeding, Dr. Larrabee's illustration was a good one, but he stopped short of the mark. A house is not necessarily well watered because it has a tank of water on top of the house. Assimilation is an important part of nutrition, and this may often be increased by proper hygienic care. Thus, fresh air, etc., are excellent, but I think I derive more benefit in these cases of feeble diathesis by massage than by any other one method of treatment. A thing that is not unknown, but I think not frequently enough thought of, in the care and management of these feeble children, is to carry the food out after it has been digested, and aid the already overworked heart and lymphatic system by assisting the circulation through the venous circulation, to get the toxins thrown off through the alimentary canal. In reference to the prevention of reinfection of tuberculosis, one practical thing that was not brought out, can be done by the physician, especially in the poorer families, namely, tell them whatever else they may do to take their carpets up and renovate them. Get them to practice hygiene daily, and I think fewer cases will occur than under any other simple means the physician can direct.

Dr. EDWIN ROSENTHAL of Philadelphia—I must tell you briefly what we do in Philadelphia. Dr. Flick read a paper on tuberculosis in the fifth ward. He noted all the houses in the district and made a diagram. I am acquainted with his work and I know in those houses emigrants came to reside and took the disease and died; not only children but adults as well. He therefore presented those papers to the county and State societies, and I believe to this Association also. In the city here we can demand from the board of health the cleansing of a house in which a tuberculous patient has died. Then we show these patients how to make cartoons to spit in and how to disinfect the sputum, etc. We have two homes for consumptives here, one for males and one for females. We also have hospitals for consumptives. We have a country home for the hospital, where most of these tuberculous patients are taken in. Then we have a seaside home for sick children, where we remove these children and give them fresh air. I believe, with Dr. Larrabee, that in an infected atmosphere we can not look for a cure. A doctor in England has written a book on the care of children. Where children are put in asylums and fed on bread, meals, etc., they will become scrofulous and afterward die of phthisis. This is a question of vital interest. In the Women's Protective Association one subject chosen was tuberculosis and its prevention.

Dr. U. J. TAYLOR of Philadelphia—In a short discussion like this not all important points can be brought up, yet I want to allude to one of great importance which has not yet been presented, that is, exercise of the right kind. The difference be-

tween man in the savage state and the man in the civilized state is that the savage and nomadic, having leisure time, spends it in sports which keep the system in good condition, the effete material all thrown out and the chest well developed. In civilization we employ our time in some sport, such as a game of cards, or we may go to the gymnasium, but even then we go to bed without expanding our lungs. If the children engage in some kind of sport in which there is a struggle for mastery, a game of ball or a wrestle or a boxing match, they exercise their muscles and their lungs. That I think is of the greatest importance and not second to any one. Fresh air brought into contact with the air vesicles in this way will do good, but fresh air brought in by twelve perfunctory breaths, I believe, as a rule will not do as much good.

Dr. DECOURCY—While the paper treated the subject largely from a preventive basis, it did not start out with what seems to me to be the first of the great list of preventive medicines. Calisthenics and climatology and all of those various branches of hygiene have been touched upon, and they are certainly absolutely necessary as preventive measures. Inhalations and lung expansions, which have been mentioned, are certainly of very great importance, yet there is a step behind all of these things which I think demands the attention of the physician. It was said by one of old that the sins of the fathers are visited on the children to the third and fourth generation, and one would think so from the tone of this paper, and truly. If that be so, then what is the physician's duty with regard to instructing his patient as to marriage and progeny? Should he advise the children of tuberculous subjects to unite, or should he advise them on either side to select a partner in marriage who is as free from inherited predisposition to phthisis as may be possible? I will be glad if the Doctor will bring out that point in closing the argument.

Dr. W. S. CHRISTOPHER of Chicago—The Doctor's paper, I think, refers more particularly to the question of the etiology of tuberculosis and incidentally to its prevention, rather than to any other factor. As at least a large part of the whole subject of pediatrics is that of prevention, it is interesting to note the phase of tuberculosis taken up by the essayist. We all know very well the methods of prevention of infection, so well carried out in some places and so little carried out in others; but the limitation of one's self to this phase must be left with unsatisfactory results, and I am satisfied the methods given by the essayist will ultimately prove much more valuable than the direct attack upon the organisms. The point brought out by Dr. Tuley I regard as one of extreme importance and I am very glad to have an opportunity to express some opinion on it. He refers to the paper recently published by Dr. Holt of New York, in which is brought out these factors: 1. A very large, and indeed very alarming, percentage of cases that die from tuberculosis present lesions within the thorax. The anatomic characteristics of this disease are to be found principally in the bronchial glands and in the pulmonary tissue. A very small percentage is to be found in the brain, a much larger percentage in the gastro-enteric tract. There are but two channels of entrance for the micro-organisms. From the fact the pulmonary glands are infected most frequently, Dr. Holt infers that the pulmonary channel is the channel through which the germ has found entrance in these cases. It is the justice of this assumption which I want to call in question. If this assumption be just, then the conclusion of Dr. Holt that the attention to the milk supply is relatively unimportant, is likewise just. But, if the conclusion Dr. Holt draws is unjust, then the relaxation of attention to the milk supply, which we are just about getting into shape, must be most horrible in its results to tuberculosis in children. Is Dr. Holt justified in saying that the germ must have gained entrance through the bronchial tract in children? He might just as well say that the lesion of variola being found on the skin, therefore the disease must have gained entrance through the skin; and the same thing he might as well say about any of the exanthemata. Does the germ of pneumonia gain entrance through the gastro-enteric or the pulmonary tract? I have seen cases in which it seemed to me to gain entrance through the gastro-enteric tract and yet produced pulmonary trouble. A child with tonsillitis has then pneumonia and this is followed by cerebrospinal meningitis which terminates fatally. The pneumonia was croupous; furthermore, the tonsillitis was a pneumococcus infection. It seems to me clear that the organism which caused the pneumonia and the cerebrospinal meningitis gained entrance through the tonsil. In that same family a child developed a diarrhea, and following that diarrhea a cerebrospinal meningitis, and died without any lesion on the part of the lung. It can hardly be doubted that these two children had the same cause for their cerebrospinal meningitis, and it points very clearly to the pneumococcus as the cause of

the condition: and, if anything, the organism which affects the lungs primarily gained entrance to the circulation through the gastro-enteric tract. If Dr. Holt's theory be correct, then how will he account for such things as primary cases of tubercular meningitis? It is no answer to the argument to say there is no such thing as a primary case of meningitis, to assume there must always be an infection somewhere else in the body, because we know that is not true. Hip joint and Pott's disease we know do occur without the lung or any other structures in the body being involved. They occur with sufficient frequency for us to know they do occur. The contention of Dr. Holt that the preponderance of lesions in the thoracic cavity proves conclusively that the germ gains entrance through the bronchial tree, is utterly untenable. He may be thoroughly right that in many instances they do, but his data do not show it. His data can not show it, and they ought not to be permitted to be extended throughout the profession and permit people to let up on the attention to the milk supply.

Dr. STICKLER (in closing)—In reference to marriage, I will simply say that if I could I would object in every case where a young man contemplates marrying a tuberculous young woman, or where a tuberculous young man contemplates marrying a young woman who is free from the disease. But that was not the point of my paper. I wished to direct your attention to the fact that it is our duty to look after the children already born. It is your duty and mine to do for these children what we ought; to save them from the disease their parents have made them liable to. We talk here freely and then we go home to our practices to attend some tuberculous mother, and there is a little child in a crib or on the floor, concerning whom we say not a word, and we do not do it simply because we are not asked to. Now, is not that true? The Good Book says, "show me your faith by your works." It is not because we do not believe in an inherited diathesis. It would be foolish to say that we do not believe in an inherited tendency to disease. The trouble is we do not act sufficiently. This has been true in my experience. I have sometimes hesitated very much before speaking to the mother about this matter, for fear they would feel that I did so looking for a fee. We should interfere oftener than we do; I do not think we are living up to what we talk of. With reference to milk, we are trying in New Jersey to do something of this kind. We have a dairy there, presided over by a committee of investigation, who look into the quality of the milk and see that the dairyman does not do that which is prejudicial to the users of the milk. There is a little trickery which we believe is being done to a certain extent. The dairyman may have a call for 300 or 400 quarts of milk, and perhaps there is only 250 quarts of milk that has been inspected. He will buy the balance of what he wants and put it into the cans and put the certified label on the bottles.

THE ADVANTAGES OF VAGINO-ABDOMINAL SECTION.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY THOMAS H. HAWKINS, M.D.

DENVER, COL.

My work in pelvic and abdominal surgery has not been entirely satisfactory. In a very large proportion of operations for the removal of abscessed tubes and ovaries, and in a smaller percentage of other pelvic operations requiring celiotomy, I have deemed it necessary to resort to drainage, and in many instances to quite extensive packing with iodoform or sterilized gauze. So far as concerns sepsis and hemorrhage the results have been exceptionally good, the mortality being reduced to about 4 per cent. In certain cases, however, I have had considerable difficulty with fistulous openings that were a source of annoyance and anxiety, both to myself and my patients. Some of these fistulae closed within a few months after the operation, others in several years, and a few are not yet filled up completely. Ventral hernia has occurred in my practice in about 12 per cent. of cases where the gauze packing and glass tubes were used.

These accidents have not been confined to my own experience. I think I may safely say that within the

past five years I have seen from two to five examples of pus-discharging openings and perhaps as many of ventral hernia for each of our prominent celiotomists in Denver. My observations also prove that these mishaps are not limited to Colorado operators. Three cases of abdominal fistula following celiotomy by Eastern surgeons, have come into my service at the Arapahoe County Hospital. I have another at the present time, operated on outside of Colorado; also one of ventral hernia. I have had the opportunity of examining, in the preceding two years, five patients with fistulous openings and three with ventral hernia ensuing upon abdominal sections performed in other States than Colorado. In short, I have encountered cases of this character from nearly all the large cities except New York. Whether the surgeons of the metropolis are so fortunate as not to have such complications or keep their poor results at home, I am not prepared to decide. Let us hope that the former supposition is the correct one. The most distressing feature of these cases troublesome sequelæ is their refractoriness to every known means of cure. Dilating and curetting these fistulous tracts is rather a formidable procedure and is by no means always successful.

I have performed vaginal hysterectomy upon two cases, one of my own and one operated on in the past, and succeeded in permanently closing the fistulous tract. Two of my cases of ventral hernia went East and were operated on by successful surgeons. They returned to Denver, believing themselves cured, but are at the present time suffering from the old affliction, which is somewhat worse than before operation. The treatment of these deplorable accidents is not within the scope of this paper, and I call attention to them only to illustrate the importance of avoiding them if possible. With the method I have pursued in most of my cases of pelvo-abdominal surgery, during the past two years, there is no possibility of the formation of fistulous openings through the abdominal wall and the danger of ventral hernia is reduced to a minimum. In every instance, when it seems likely that drainage or gauze packing will be required, I precede the abdominal with a vaginal section. This combined method is in no sense original with myself as, to my knowledge, many others have resorted to the same plan.

The patient is placed on the table as for an ordinary vaginal operation, and the abdomen and genitalia are rendered as nearly aseptic as possible. The uterine cervix is hooked, its canal mopped out with sterilized gauze dipped in bichlorid solution, and then curetted. After gentle dilatation, so as to admit a curette of medium size, the uterine cavity is curetted carefully, dried with sterilized gauze and washed out with a weak solution of iodinated water or creolin. This is followed by a sterilized salt solution, and the cavity is again thoroughly dried. The cervical canal is packed with a bit of iodoform gauze. A semicircular incision is now made posteriorly, close to and half way round the cervix, into the cul-de-sac. If time permits, I sometimes stitch the peritoneal membrane to the vagina by means of a catgut suture; then, with my finger I proceed to explore the pelvic contents, breaking up adhesions, slowly and cautiously separating the uterus from the mass on either side and severing, as far as practicable, from below upward, all the false attachments of the ovaries and tubes, as the case may be, taking care not to rupture the abscesses

or cyst, if these be present. In many cases, where simply large abscessed tubes or ovaries are found, or a hydrosalpinx, or a small ovarian cyst, this is evacuated and the pelvic cavity is washed out thoroughly and packed with gauze, no further procedure being required. When the lesions are more extensive, after as much is accomplished through the vaginal route as seems prudent, the wound is thoroughly flushed and dried out with sterilized gauze, with which it is then quite snugly packed and the vagina moderately so.

The patient is now drawn up on the table in the position for celiotomy. The incision through the abdominal wall need not ordinarily be more than two and one-half inches long, as the previous vaginal performance greatly simplifies the operation by allowing the uterus and its appendages more easily to be freed from adhesions and brought into view. The diseased adnexa are removed and the pelvic cavity is dried in the usual way, the gauze below not being disturbed.

In only one instance, in which the hemorrhage was inordinate, have I found it necessary to employ abdominal packing, which was removed at the end of thirty-six hours and the incision closed. In all the other cases, numbering thirty-five, of the combined operation I did no packing through the abdominal wound, an election fully justified by the results.

After completing the work from above, a moderate quantity of gauze is packed into the pelvic cavity, behind the uterus, and is pushed in more closely where there is much oozing. I generally utilize iodoform gauze for the first two or three strips, filling in with the sterilized variety. The stitches are now taken in the abdominal wound, which is closed hermetically by drawing the sutures firmly and catching them fast with forceps. The patient is again brought down into the usual position for vaginal procedures, the gauze packing is removed from the vagina and pelvic cavity, and the parts are once more carefully cleansed and dried. Fresh iodoform or sterilized gauze is now packed well up into the pelvic cavity and is made to fill the vagina snugly. A pudendal pad is next applied and held in place by the nurse's aseptic hand while the abdominal wall is re-opened. The gauze put in from above is quickly removed; rapid inspection is made for hemorrhage; and the wound is permanently closed, uniting the fascia with a continuous chromicized catgut suture, ordinarily, unless there is reason to speedily terminate the operation. With trained assistants and a skilful anesthetic, with everything in readiness in a well-equipped hospital operating room, the combined operation can be done, as a rule, in from twenty-five to fifty minutes. When one has performed the operation three or four times, its duration probably need not exceed that of a simple celiotomy for the removal of diseased uterine appendages. It takes perhaps a minute more to clean and dry the genitals, three or four minutes to dilate the cervix and curette, and one or two minutes for the vaginal incision. The time occupied in separating the adhesions from below and putting in the gauze packing is amply compensated when the tubes and ovaries are about to be removed through the abdominal wound.

The more expert operators, especially the Eastern ones who are doing pelvic sections every day, may not appreciate the advantage gained by the breaking up of the adhesions from below, but in my own somewhat limited experience, I have found that this method enables me to remove the uterine appendages

in about the same length of time as I formerly needed to do the operation entirely from above, a consideration of special importance to us less adept gynecologists of the West. Out of the thirty-five cases operated on by me by the combined method, I have had but one death, which was in no sense attributable to the operation. The patients suffered rather less than former ones. With a single exception the temperature never rose above 99.5, in this case the temperature (reaching 103 on the fifth day and normal on the seventh) being affected by a severe cold and tonsillitis. In every instance the gauze was removed on the third day, and the vagina flushed with warm sterilized water, loosely filled with aseptic gauze and covered with a sterilized pad. I repacked the opening into the cul-de-sac, as a rule, not more than once, and then only with a small strip of gauze. The dressing on the abdomen may remain undisturbed until the fifth to the eighth day.

Every possible objection to the combined operation is, I think, offset by its advantages. A special point in its favor is that when the conditions, as determined through the vaginal incision, permit, we may forego abdominal section and thus greatly lessen the risk. To illustrate: During the period of the above mentioned thirty-five surgical cases I had no less than twenty other patients in whom the cul-de-sac procedure alone sufficed. In one instance I found a cyst of the ovary, ruptured it, irrigated and put in gauze. The patient's temperature was normal throughout and she made a perfect recovery. Another case was that of a hydrosalpinx which I broke open during exploration. The cavity was washed out carefully, dried and packed with gauze, and the woman recovered without complications of any kind. On eleven occasions I tapped abscessed ovaries or tubes, washed them out and drained through the vagina. In one case I found an abscessed tube well down into the cul-de-sac. It was evacuated, enucleated and tied off close to the uterus and removed. The other tube and both ovaries were in good condition. The patient was flushed and drained and recovered without any bad symptoms. In three cases I opened into what was probably a ruptured tubal pregnancy of several weeks standing. The decomposed clots and other debris were thoroughly removed by the fingers and irrigation, and the space was packed with iodoform gauze. These patients recovered without a single bad complication. Finally, in three instances I found no special lesion, except adhesions, about a retroverted uterus. These were carefully and completely broken up and a large amount of gauze packed behind the uterus, which had been pushed forward as far as possible. The convalescence in these cases was short, and complete relief ensued, with the uterus in a better position. All these cases were treated successfully by means of a very simple operation, whereas abdominal section would have been accompanied by much greater risk and probably without as good results.

In complete hysterectomies, where there is extensive oozing and reason to fear hemorrhage, in one or two instances I have thought it best to use packing from above; I have pushed the gauze well down into the opening through the vault of the vagina, then filled the vagina from below. At the end of the first or second or third day, as deemed best for the removal of the gauze, the vagina is emptied and carefully washed. The end of the gauze protruding through the abdominal wound is cut off close to this incision;

the part remaining may be softened with a little sterilized water. By means of a tenaculum or dressing forceps the residue of gauze is then pulled out *per vaginam*. The incision in the abdominal wall is now closed, and the pelvic city and the vagina are again packed from below.

SOME REFLEX DISTURBANCES DUE TO PELVIC DISEASE.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN MILTON DUFF, M.D.

PITTSBURG, PA.

Reflex disturbances in the human body from whatever cause, are generally a great source of annoyance to the practitioner. Especially is this the case when the original disease does not present marked symptoms, or at least where the reflex disturbance overshadows the real disease. These conditions make the diagnosis difficult and consequently the treatment is often misdirected. I will briefly report a few cases in point:

Case 1.—Patient (A 3474, South Side Hospital case-book), Mrs. A. N., age 39 years, married fifteen years, no children. Family history good and excepting ordinary diseases of childhood has always been healthy until two years ago, when she began to show symptoms of chronic inflammatory pelvic disease. For the past three months she has been suffering from insomnia, sleep being procured only by the use of hypnotics. For some time her mental condition has been bad. Her conversation is now very incoherent. She has a high temperature, rapid, feeble pulse, great tenderness on pressure over the suprapubic region. Bimanual examination reveals enlarged and tender ovaries, tubes and uterus. On April 6, 1896, I removed the uterus and appendages by the vaginal route. She made an uneventful recovery. At the end of three weeks her mental condition was apparently normal. Eight months later, the last report I had from her, she had gained over fifty pounds in weight and expressed herself as in perfect health physically and mentally.

Case 2.—Patient (A 2923 South Side Hospital case book), Mrs. C. Z., age 30 years, married ten years, mother of four children; chronic ovaritis and salpingitis; mental condition good. I removed her uterine appendages Sept. 16, 1895. She made an uneventful recovery and left the hospital, presumably well, Sept. 22, 1895. Three weeks afterward I was called to her father's house to find her suffering from violent mania, having attempted but a few hours before to commit suicide by cutting her throat. At the end of one year this woman had returned to a normal condition of health. This is the only case of which I am aware in which mental aberration followed the removal of the appendages in my practice.

Case 3.—Patient (A 4081 South Side Hospital case-book) Miss E. Mc., age 27 years; health always good until within past three months, when she began to be affected with nausea and occasional vomiting after eating. For the past two weeks the stomach rejects all food and in order to sustain life nutrient enemata have been resorted to. Examination revealed a cystic ovary, which I removed on Dec. 4, 1896. The patient left the hospital Dec. 27, 1896, apparently well, not having vomited any since the second day after the operation. At present she is in excellent health.

Case 4.—Patient (A 4075, South Side Hospital case-book), Mrs. S., age 48 years, mother of two children, youngest 20 years old; has history of pelvic disease for five or six years. Her trouble was not sufficient, however, to keep her from her household duties, except for short periods of time, until July 1, 1896. At this time she was attacked with nausea and vomiting. Dr. Boyd of Knoxville, Pa., was called to see her. After exhausting his resources medically, as well as those of a number of practitioners who were called in consultation, without avail, the patient was removed to the South Side Hospital on Nov. 30, 1896. At that time she was scarce more than a living skeleton. She had been nourished entirely *per rectum* for eighteen weeks, the stomach during this time apparently rejecting everything, even to water. Her condition was such that I hesitated to attempt any operative procedures. My colleagues on the staff advised against it, as they did not think she could even bear the anesthetic. She and her family, who

had persistently refused for several weeks to allow an operation, insisted that she be given the chances. On Dec. 2, 1896, I removed two large pus tubes and cystic ovaries. Her recovery from the operation was slow, as the wound became septic, she not leaving the hospital until Feb. 8, 1897. She, however, never vomited after the third day following the operation. She was in my office a few days ago, has regained her normal weight and is now attending to her ordinary household duties.

Case 5.—Mrs. K. M., age 32 years, mother of three children, the youngest 4 years old. She has had symptoms of pelvic disease for three years. Her principal trouble, however, is that she has been almost a constant sufferer from sciatica on the right side for two years. One year ago her uterus was curetted and cervix repaired, after which she rapidly grew worse. For the past six months she has been unable to leave her room except when carried down stairs. She could only walk with help on the level floor. On Dec. 10, 1896, I removed the right ovary, which was cystic and generally adherent. She was discharged from the hospital Jan. 12, 1897, free from sciatica and able to walk without help. A few days ago she came by herself on the train and without inconvenience walked several squares to my office.

Case 6. Patient (A 4360, South Side Hospital case book), Mrs. S. Mc., admitted May 8, 1897. Examination revealed a chronic inflammatory condition of the uterus and appendages. The patient dates her trouble from her last confinement, eight years ago, since which time she has been having occasional epileptoid seizures. For the past two years these seizures have become more frequent, sometimes occurring five or six times during the month, their occurrence being more frequent near the menstrual period. For several months she has been suffering from insomnia and has been in such a nervous condition that she could not be induced to remain alone during her waking hours. On May 12, 1897, I removed her uterus and appendages by the vaginal route. In this case, as only eighteen days have elapsed since the operation, it is too soon to draw conclusions. At the present time the patient is up, walking about the room and says she feels splendid. She has not had a convulsion since the operation. She eats well, is perfectly free from pain and has slept well for the last twelve nights. She will now remain alone without comment. To use her own words, as she expressed them to the Chairman of this Section when he visited the hospital a few days ago, "All that fear and ugly feeling has gone and I believe I am a new woman."

I have thus presented these few cases without minutiae, hoping they may form a nucleus for a discussion upon this, to me, interesting subject. I do not wish it to be inferred that in my practice all cases have been as successful as those reported; such would be far from the facts, as I have frequently been disappointed in results.

A CASE OF FIBRINOUS BRONCHITIS.

Read before the Chicago Pathological Society, October 1897.

BY JOSEPH M. PATTON, M.D.

PROFESSOR OF INTERNAL MEDICINE, CHICAGO POLICLINIC.

AND MAXIMILIAN HERZOG, M.D.

PROFESSOR OF PATHOLOGY, CHICAGO POLICLINIC,
CHICAGO, ILL.

Chronic essential (primary) fibrinous bronchitis, croupous bronchitis or bronchitis pseudomembranacea is a rare affection. Its rarity is commented on by every observer of the disease, and is sustained by the small number of cases reported, no observer having seen more than one or two cases.

Birmer¹, who wrote the first extensive monograph on the subject in 1855, says: "Bronchitis crouposa is a very rare affection." Galen² observed a case of bronchitis fibrinosa, though he erroneously described the bronchial cast which he saw as a coughed up pulmonary blood-vessel. Tulp³ in 1641, presented the first reliable report on fibrinous bronchitis. He described the fibrinous exudate as *sarculi rane arteriosae expectorati*, and illustrated his report by two drawings which do not leave any doubt as to the nature of the affection. Morgagni⁴, in 1760, described fibrinous bronchitis.

Birmer (loc. cit.) gives an elaborate description of fibrinous bronchitis based on a series of fifty-eight cases, of which number fifty-six were collected by him from literature. Two cases came under Birmer's own observation.

An extensive monograph on fibrinous bronchitis, with a complete list of the literature pertaining thereto, is found in the chapter on this subject by Riegel⁵ in Ziemssen's "Handbuch." In 1893 an extensive article was published by Beschorner⁶ in which we find the first contradiction of the generally accepted view of the fibrinous nature of the exudate expelled in the form of bronchial casts in fibrinous bronchitis.

In the case reported by Beschorner the microscopic examination was made by Neelsen, who found that sections taken from the casts when stained according to Weigert's formula did not, as they should if composed of fibrin, display a blue color, but became a pale gray. Beschorner, therefore, maintains that the material from which the casts are formed is not fibrin but mucin, and he draws a parallel between the conditions found and the exudates formed in bronchitis fibrinosa and those in enteritis pseudomembranacea.

Similar conclusions are arrived at by Grandy⁷ an American, who quite recently, under Weigert's direction, examined microscopically a case of bronchitis crouposa which came to postmortem.

Grandy's report is as follows: Stains of sections from casts; no color with Weigert's stain for fibrin. With thionin there resulted a weak rose color, but formalin preparations do not stain well with thionin. Sections from the bronchi: One can see distinctly how the exudate makes its way from the excretory ducts, and from there into the bronchi, that is into the bronchial exudate.

The exudate in the bronchi and in the goblet cells give the reactions characteristic of mucous: *light blue* with Van Gieson's stain, *rose red* with thionin and rather dark brown with Bismarck brown.

Farther away from the walls of the bronchi the exudate was changed and did not show the characteristic stain. Thoroughly negative was the result with Weigert's fibrin stain. The mass never stained a beautiful blue like fibrin would do, but invariably stained a pale gray like the ordinary tissue.

The results of the examinations of Beschorner, Neelsen and Grandy stand in opposition to the statement of Klebs,⁸ who maintains that the exudate in bronchitis crouposa is of a true fibrinous nature. Eppinger⁹ expresses the same view as Klebs, and bases his opinion on the result which he obtained with Weigert's fibrin stain.

In the case which we can add to the list of cases of bronchitis fibrinosa already published, the result of the examination of the exudate is such that we must claim that the latter is of a true fibrinous nature and consists of true fibrin.

Unfortunately, chemic tests were not made while the exudate was fresh. Still, the tinctorial tests are so decided in their results that they leave no doubt as to the fibrinous nature of the exudate.

The clinical history of the case (presented through the courtesy of my clinical assistant, Dr. Gottschalk) is not as complete as could be desired, but as far as could be obtained is as follows:

Male, aged 40, married, beer bottler by occupation. Was perfectly well until two years ago, when he caught cold while working in a wet place. During the last two years he has had repeated attacks of bronchitis.

These attacks would last a week or ten days, and were characterized by rather severe rasping cough. Expectoration was comparatively free, and there was no particular pain in the chest. About ten weeks before his recent attack he began to cough and expectorate large masses of tough, tenacious sputum, which was accompanied at times by some bloody expectoration. About four weeks before the expectoration of the cast, he developed high fever, great dyspnea and a distressing cough. There was diminished expansion and dullness over the lower two-thirds of the left lung as compared with the right lung. This attack lasted between three and four weeks, and continued up to the time of the expectoration of the bronchial cast. During this period he was confined to bed and suffered with severe dyspnea, cough, and a temperature at times above 102 degrees F.

Three days ago he expectorated considerable blood. The temperature remained high and the dyspnea and cough distressing.

This morning he had a severe attack of dyspnea and coughing. Temperature rose to 104 degrees F. After considerable effort he expectorated a large mass

obtained, two tubes containing Loeffler's blood serum mixture were inoculated at once and placed in the brood-oven for twenty-four hours. These tubes did not develop any diphtheria bacilli, but colonies, which consisted of large round micro-organisms, probably yeast cells or a species of torula.

The exudate as obtained consisted of a cast of the bronchial tree, of a total length of over 10 cm. Its main short stem, which is about 1 cm. long, is about as thick as a lead pencil and the branches run out to fine filaments. They, however, do not all terminate in a very fine thread, but some, at their ends, show a dilatation which probably represents a cast of an infundibulum. The larger branches here and there show nodular prominences. The larger tube-casts, when examined in cross sections, show a more or less cen-

Bronchial cast from case of fibrinous bronchitis.

of material which consisted of the bronchial cast mixed with mucous and quite a little blood. The temperature became reduced almost immediately, and the cough and dyspnea were relieved.

Within a very short time after expectorating the cast an examination, made by Dr. Gottschalk, showed that air was entering all parts of the left lung with comparative freedom. The percussion note was almost normal, and there were mucous râles to be heard over both lungs. The patient improved rapidly and all trace of him was subsequently lost, so that it is impossible to tell what his present condition is.

In view of the marked tendency of these exudations to recur, the subsequent history of this patient would be interesting, could it be obtained.

Pathologic report.—When the fibrinous casts were

examined, two tubes containing Loeffler's blood serum mixture were inoculated at once and placed in the brood-oven for twenty-four hours. These tubes did not develop any diphtheria bacilli, but colonies, which consisted of large round micro-organisms, probably yeast cells or a species of torula.

Pieces of the casts were hardened in alcohol, and also in formalin with subsequent alcohol hardening and stained according to different methods.

1. *Gramm's stain.*—The following micro-organisms were found in sections stained according to Gramm: Staphylococci, large bacilli with square ends (about 5 to 7 μ or more long) uniformly but slightly stained; smaller bacilli (3 to 4 μ) having stained very deeply; small bacilli (2 to 3 μ) with rounded ends, which have not taken the stain uniformly; large spherical micro-organisms looking like saccharomyces or torula.

2. *Weigert's formula for fibrin stain*.—The great bulk of the mass of the exudate which shows a fibrillar arrangement, stains beautifully blue, giving a typical fibrin stain.

3. *Hematoxylin*.—The great bulk of the tissue takes a deep hematoxylin stain.

4. *Van Gieson stain* imparts to the tissue a reddish brown color.

5. *Altmann's acid-fuchsin picric acid stain* for granula and fibrin produces a vivid red color.

From the enumeration of the stains used and the results obtained, it is evident that the casts consist of fibrin. Mixed with it are found swollen degenerating epithelial cells and a considerable number of leucocytes.

Optical test.—Small pieces of the casts, after hardening, were washed in distilled water and then teased on a slide and covered with a cover glass, and the effect was watched under the microscope. The tissue became somewhat transparent, though not very much so.

Chemical test.—Two decigrams of the hardened casts, after being well washed in distilled water and subsequently dried between filter paper, were subjected to the action of 10 c.c. of artificial gastric juice. After being in the brood-oven for three hours the exudate so treated had been completely digested. Mucin under these circumstances would not have been digested.

All the tests employed, therefore, had furnished results establishing beyond a doubt the fibrinous nature of the exudate expelled in our case of bronchitis crouposa.

A NEW BINAURAL STETHOSCOPE WITH ARMAMENTARIUM FOR COMPLETE PHYSICAL EXAMINATION.

Demonstrated before the Medico-Surgical Society of New York, Nov. 8, 1897; and before the German Medical Society, Dec. 6, 1897.

BY S. A. KNOPE, M.D. (PARIS AND BELLEVUE, N.Y.)

Physician to the Lung Department of the New York Throat and Nose Hospital; Former Assistant Physician to Professor Dettweiler, Falkenstein Sanatorium, Germany; Fellow of the New York Academy of Medicine; etc.

NEW YORK.

On March 16 last, I demonstrated to the Section of General Medicine of the New York Academy, an improved stethoscope with an attachable plessimeter.¹ Its daily use since then has shown me some of its imperfections and I have been working for months on the instrument with the object to improve it and above all simplify its use. I am able this evening to present to you the result of my labor, thanks to the courtesy which you extend to me as your guest, and since the instrument differs in all its details from any one thus far devised I may perhaps call it "a new binaural stethoscope."

You will see at a glance that it has neither eartips nor front springs, nor the heavy metal conducting tubes of the ordinary binaural stethoscope. Among

students and in hospital services it is not infrequent that one stethoscope passes from ear to ear, and I wonder if the eartips may not have been in some cases the cause of transmitting the various parasitic organisms which are so frequently found in the external auditory canal. But there is no doubt that among physicians who auscultate a great deal every day the constant pressure of the eartips in the canal produced by the large powerful frontspring, and the unpleasant weight of the metal conducting tubes bearing down upon the delicate membrane, often cause discomfort amounting at times to severe pain in the external meatus. I know of a great clinical teacher and world renowned diagnostician of heart and lung diseases who ascribed the partial loss of his hearing to the use of the binaural stethoscope with the powerful frontspring attached to the heavy metal tubes, and to the irritation produced by the presence of the painful eartips. All these inconveniences which the old

binaural stethoscope presents I believe to have effectually overcome. I have adopted an elastic, easily adjustable steel headspring *a*, to which are attached two well-fitting earpieces *b*, covering the external ear, and to which in turn are attached light flexible conducting tubes *c* and chestpieces. Finally, I have discarded the eartips entirely. To exclude external sounds I had devised, for my first stethoscope, round earpieces, which, however, did not fit every ear; I have replaced them by shell-shaped pieces more corresponding to the average conformation of the auricle; and to make the adaption of these earpieces to the temporal bone still more exact, I had them joined to the headband and conducting tubes by a ball and socket joint *d*.

To dampen the external sounds still more, and not have the conducting power suffer, I have these earshells and the angular connecting pieces *c* covered, according to Knapp's excellent method² with vulcan-

¹ New York Medical Record, May 1, 1897.

ized rubber. As conducting tubes I have adopted a flexible air-tight soft rubber tubing, on the inside of which a round coiled wire is placed, and over the whole a silk covering is woven.

The acoustic power of the instrument when in use, I believe, to have considerably increased by having the connecting joint *f* and all the bells and the other chestpieces which serve as receivers and transmitters of the sounds emitted from the thoracic or abdominal cavity, made also of metal, and covered as the earpieces, with vulcanized rubber.

To make the stethoscope as convenient as possible it is made so that it can easily be taken apart and placed in a medium sized coat-pocket and rapidly put together again, ready for use. One chestpiece in the shape of a bell suffices for ordinary examination, and this can be left on the connecting joint *f* most of the time. Occasionally, however, we desire to make an especially careful examination of either lungs or heart, and to this end I have devised a little armamentarium which includes all that may be needed to make a most careful physical examination of either thoracic or abdominal cavity. Instead of the attachable plessimeter of my former instrument, I have modified Constantine Paul's suction-cup *g* for the purpose of combining instrumental percussion and auscultation. It consists, as you see, of a rubber ball, tube and cup-shaped chestpiece, easily attached to the stethoscope. By pressing the rubber ball a sufficient vacuum is produced to have the piece retained in its position, enabling one to auscultate and percuss at the same time. But the greatest advantage of this combination lies in procuring absolute contact and stability with the cutaneous surface and thus the exclusion of all other external sounds. Besides, for studying as well as for teaching complicated heart sounds it is often convenient to have the chestpiece remain stationary. With a little care several students may alternately put on the headband and earshells without disturbing the chestpiece retained by atmospheric pressure over the point where the abnormal sounds are best perceived.

For lung auscultation I have a somewhat larger bell *h* than the one designed to auscultate the heart, *i*, and for intercostal auscultation this somewhat oval-shaped chestpiece *j* will prove rather convenient. For sensitive chests and for children the soft rubber-bell *k* should be used. It can easily be attached to the heart bell. To define when necessary a very small and circumscribed area of pathologic changes by auscultatory means I have replaced the localizer of the phonendoscope by a little instrument which I call the delineator *l*. When attached to the stethoscope it may not equal the phonendoscopic sounds in loudness, but since it is minus the sound-perverting vibrations, produced by the diaphragm of the phonendoscope, the careful listener will hear all he need to, and this little instrument will certainly serve its purpose quite well in the majority of cases. All the various supplementary chestpieces for lung, heart and intercostal auscultation, the delineator, etc., are finished so that a simple insertion is all that is necessary for their attachment to the stethoscope.

While a plessimeter is not an absolutely indispensable instrument, clinical teachers and all who do a good deal of percussing, will find it at times a great relief in conjunction with a good percussion hammer. The possibility of acquiring a periostitis of the left

index finger by using it constantly as a plessimeter, may thus also be averted. I have attached a convenient handle *m* to a hard rubber plessimeter *n*, and as hammer I give Flint's well-known percusser *o* the preference.

It remains only for me to thank Messrs. Tiemann & Co., for their courtesy in repeatedly altering my stethoscope until it became, what I think, a nearly perfect instrument for mediate auscultation. May it find favor with the profession and serve its purpose well.

955 Madison Avenue.

APPENDICITIS COMPLICATING OVARIAN CYST AND SIMULATING TORSION OF THE PEDICLE, WITH THREE CASES.

Presented in the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY X. O. WERDER, M.D.

PITTSBURG, PA.

Appendicitis as a complication of an ovarian cyst and accompanied by symptoms strongly resembling those of torsion of the pedicle, does not seem to be of very frequent occurrence; at least I have failed to find any cases recorded in the literature at my disposal. This is my excuse for reporting the following cases which came under my observation and in which the symptoms were supposed to be due to an axial rotation of the tumor when, on the operating table, an appendicitis was discovered to be the disturbing element which led to a wrong diagnosis.

Case 1.—Mrs. C., age 56 years, mother of nine children; one miscarriage; last confinement sixteen years ago, followed by fever; otherwise always healthy. Her present trouble dates from May, 1894, when she was seized with cramps in the abdomen and vomiting, which continued for several days. She had at times most of her pain in the right side. She has had several attacks since then of a similar nature, in the last of which she was attended by Dr. A. Koenig, who discovered a tumor in the abdomen. When I saw her in consultation with him, her acute symptoms, pain, vomiting, temperature 103 degrees, had somewhat subsided, though her abdomen was still very tender on pressure, and tympanitic. It was enlarged by a tumor occupying nearly the mid-region, more to the left, indistinctly fluctuating and painful on palpation. The diagnosis as made was: Ovarian cyst, with possible torsion of pedicle. Her removal to Mercy Hospital was advised for the purpose of operation.

Operation, Aug. 13, 1894. On the right and upper surface of the tumor the omentum and several feet of small intestine with the vermiform appendix, were adherent. The latter was not much enlarged, but congested and filled with pus. It was ligated and cut, and the stump covered by a peritoneal sleeve. The adherent intestines were separated with considerable difficulty, many points requiring suture with fine silk to control bleeding. The cyst wall was unusually red and congested. Convalescence was interrupted by an attack of pneumonia at the base of the right lung, on the fifteenth day. The patient was discharged cured about six weeks after operation.

Case 2.—Mrs. K., age 39 years, mother of seven children, youngest 5 years old. Shortly after last confinement she noticed a lump in the right iliac region that has been gradually growing larger. She was seen in consultation with Dr. Potter Dec. 1, 1896. Two weeks previously she was seized with severe cramps in the lower abdomen, accompanied by vomiting and followed by high fever. The abdomen became tympanitic and extremely painful and tender, requiring frequent opiates to give relief. These symptoms abated during the last few days, though the abdomen, and especially the tumor, were still quite painful to the touch. The tumor occupied the middle of the abdomen, extending above the umbilicus, and showed indistinct fluctuation. She was removed to Mercy Hospital for operation, which was performed Dec. 6, 1896.

The cyst walls were dark in color and the seat of extensive adhesions to abdominal walls, intestines and pelvis. The adhe-

sions were freed, bleeding points of omentum ligated and removed. The appendix, which was about six inches by one half inch thick, hard, red and adherent to cyst, was freed, the meso-appendix ligated near the cecum, stripped from the distal end of the appendix; the appendix also ligated near the cecum, clamped one half inch further out and removed by cutting between; stump mopped and covered by meso-appendix which was stitched over it. Convalescence was uneventful; out of bed the twenty-first day, discharged the twenty eighth day.

Case 3.—Mrs. Wm. E. F., age 44 years, mother of three children, youngest 6½ years old; normal convalescence. Last October, after some exertion, she noticed a swelling in her abdomen, which has remained ever since. February 26, I saw her in consultation with Dr. Ryall, who had been attending her through an attack which was started by severe abdominal pains and vomiting, which kept up for several weeks; retention of urine, abdomen tympanitic and very tender. She was very much emaciated and quite feeble, though her acute symptoms had pretty well subsided, excepting her temperature, which remained above normal.

Physical examination showed a fluctuating tumor, filling up the pelvis and abdomen, of the size of a pregnant uterus at six or seven months, which was very tender on pressure. She was removed to Mercy Hospital February 28 and operation performed March 4, after vainly trying to improve her general condition. Extensive omental and intestinal adhesions were separated from the cyst; pelvic and uterine adhesions very firm and difficult to separate, leaving a torn and bleeding uterus. An elastic ligature was therefore passed around it, the body amputated, treating the stump extraperitoneally. The cyst, which was multilocular was exceedingly friable, breaking to pieces at the least touch, in a number of places. Its walls were dark colored, from one-half to one inch in thickness. Microscopic section showed the cyst wall to be necrotic. Contents of the cyst were semisolid, of dirty gray color.

The appendix was adherent to the cyst, tense, enlarged and inflamed, containing an enterolith. The microscope showed catarrhal inflammation. The patient had lost considerable blood during operation and was pretty well collapsed when taken from the operating table, but gradually rallied under active stimulation and improved.

March 7 she showed undoubted evidences of double pneumonia and was in a critical condition for five or six days. She finally improved and made an excellent recovery.

The pneumonia occurring in these two cases was a mere accidental complication, though the lowered vitality and the forced recumbent position for weeks even before the operation, no doubt greatly contributed to its development.

The symptoms, in connection with the knowledge of the presence of an ovarian tumor in these cases, certainly justified the supposition that the complication was due to torsion of the pedicle; especially as the acute stage of the trouble had passed at the time they came under observation. Differentiation would probably have been easier at an earlier stage, as long as the inflammatory area in appendicitis was more localized. The fact that in torsion of the pedicle there is usually a rapid increase in the size of the tumor, marked shock and perhaps a less prompt rise of temperature than in appendicitis, would also probably be of considerable value in differential diagnosis at the outset, but at a later period the symptoms of the two conditions, at least in the cases in which torsion of the pedicle does not lead to a rapidly fatal termination, are so similar that it would scarcely be possible to differentiate them. Fortunately both conditions demand the same treatment *i.e.*, prompt operation; and a differential diagnosis has, therefore, more of a scientific interest than practical importance.

A fact worth noting is that there was undoubted inflammation of the cyst in all cases; in the last two cases this was particularly pronounced, as evidenced by the dark red discoloration of the cyst and the marked thickening of its walls and its unusual friability; in the last case they were actually necrotic in numerous places; conditions strongly resembling those

found in torsion of the pedicle and in malignant disease. Malignant degeneration was seriously suspected, but the microscopic examination was negative on this point. There were no evidences of fresh hemorrhagic effusions into the cyst cavity in any of them. That this inflammation of the cyst cavity was not merely an extension by contiguity seems to be demonstrated by the fact that not only a portion of the cyst, the one in contact with the adherent appendix, was involved, but that the whole neoplasm seemed in a state of active inflammation with marked hyperemia and thickening of its walls, and in one, even at least partial necrosis. We must, therefore, suppose that the inflammation was caused by an infection from the appendix and not by a simple extension of the inflammatory process.

In conclusion, I wish to call attention to the method adopted in treating the stump of the appendix in the last two cases. It is so simple that doubtless it must have been used before me by other men, though I have been unable to find any account of it. It consists in tying the meso-appendix and the appendix separately near its insertion into the cecum. The meso-appendix is then stripped of the distal portion of the appendix down to its ligature, the latter cut off about half an inch above, and the stump covered with the freed meso-appendix, and attached by one or two superficial sutures. By this means the whole stump is completely buried under a layer of peritoneal tissue. This can be done with more rapidity than by inversion or covering the stump with a peritoneal sleeve, and it certainly answers the purpose in every respect. I have followed this plan in all my cases requiring appendicectomy during the last six months, where the meso-appendix had not sloughed away. It has been perfectly satisfactory.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

(Continued from Vol. xxix, 1315.)

XIX.—DISEASES OF THE URINARY AND GENITAL ORGANS
AND OF THE RECTUM.

Ischuria was studied with great assiduity by Desault, whose classic essays (*Jour. de Chir.*, i, ii) Richter transferred in part verbatim to his "Elementary Principles." They distinguished: 1. Paralytic retention of the urine, which appeared chiefly in old people, and from that arose the fact that the bladder lost the power of contracting. It might also be the result of venereal excesses, onanism and spinal injuries. External stimulants (Spanish flies, arnica and cold applications on the perineum) were valued, especially the continued use of the catheter to empty the urine. It seemed best to retain flexible catheters, stop up their openings and allow the urine to flow out every three hours; then about every sixth day to take them out and clean them. In case of a long continuance of the trouble it was advised that the patient learn to catheterize himself. 2. Inflammatory ischuria implied the inflammation of the neck of the bladder, the urethra or the rectum. It arises from stone, hemorrhoids, rectal fistula, contusion of the perineum, rheumatism and most frequently in a so

called obstructed gonorrhea. For this they used antiphlogistic remedies (calomel with opium), warm baths, poultices applied locally; after these the catheter, which, however, must not be left in place; in the worst event, puncture of the bladder. 3. Spasmodic retention of the urine, which had its seat in the neck of the bladder and was treated with antispasmodic remedies. 4. That from the obstruction of the urethra in consequence of foreign bodies. For the extraction of these J. Hunter devised the best adapted instrument consisting of a small tube, out of which two arms, spreading by means of a spring, were pushed forward. Desault also invented tweezers, almost like this, only they were larger and curved like a catheter. If extraction failed then nothing was left but to cut open the urethra. A wound in it healed readily if the urine were kept from it by a catheter. 5. Suppression of urine by strictures of the urethra. These were mostly in front of and near the bulbous, but might occur in several places. The causes were regarded as mostly "venereal inflammations of gonorrhea," until J. Hunter, in an accurate work on stricture, showed that it was not the fault of a special poison, but that constrictions might arise after any inflammation in the urethra. He divided them into permanent, which depended upon an organic defect, and spasmodic and mixed. The treatment was with bougies, "one of the most important inventions of recent surgery" (Richter), to which Hunter and Desault turned their full attention. The best bougies consisted of linen which was dipped in a mixture of wax, olive oil and minium, smooth and pliant; they did not break easily and were preferred to the usual wax bougie. Besides there were a countless number of compositions for the preparation of bougies. Catgut was also used; it had the advantage not only in distending the stricture but also in softening it, but was often hard to insert, caused severe pain and was easily worn out. Lead wire was also difficult to introduce and painful and easily took a wrong course. The patients soon became accustomed to the bougies, which were at first borne only a quarter of an hour, so that each day they were pressed in farther. From their premature use an abscess might arise at the stricture which either should not be opened at all or as late as possible (Desault); they might also take a false course. Perfect cure was seldom reported before three or four months and a relapse was not infrequent. If the treatment with bougies failed then Hunter recommended corrosives; he touched the stricture with a small piece of nitrate of silver every day or two until the probe pressed into the bladder. Desault regarded this treatment as uncertain and dangerous and never ventured to use corrosives. Richter also considered it unnecessary in most cases, since the bougie would finally press through. For abnormal duplicatures running clear through the urethra both surgeons recommended a turning of the catheter on its axis, but considered the so-called bougies *médicamenteuses* to no purpose in suppression of the urine. 6. There was an ischuria in consequence of swelling of the prostate occasioned by inflammation, abscess, stone, varices or scirrhus of the gland. If the dispersion of the inflammation was not quick enough the application of a catheter with a considerably bent point was necessary. But rather than apply force in such a case it was said to be better to decide upon a puncture of the bladder. The abscess lying at the surface of the prostate for the most part breaks spon-

aneously or the catheter opens it; situated between the gland and the rectum it was to be reached through the latter. If it opened into the bladder or urethra they left the catheter in position and injected a thinned barley water in order to wash out the pus. If they felt stony concretions in the prostate, which was, however, very difficult, an incision was made in from the perineum. In case of varicose swellings of the vessels of the gland catgut was the best. The most frequent tumor of the prostate was the scirrhus induration, as it occurred for the most part in old people who had had gonorrhea in their youth (Richter). For this they used thin silver catheters, rubbing with mercury salve, a seton in the perineum (Hunter) and as a last resort the *boutonnière*. This operation, the technique of which resembled that of today, found many opponents, among them Desault, who considered it for the most part superfluous and declared that it had, with right, sunk almost entirely into oblivion. Besides these main groups of ischuria, Desault described one which originated in the ureter as foreign bodies, inflammation, swelling or ulcers which compressed it. Since these causes were for the most part only discolored after death, art could do but little; further, the surgeon recognized suppression of urine as a result of retroversion of the uterus, prolapsus of the uterus and of the rectum and pregnancy.

In the most urgent cases of ischuria one must have recourse to puncture of the bladder. This operation in itself without danger, surgeons at that time employed much more frequently than at present, because they overcame the obstructions in strictures with greater difficulty and did not appreciate the uses of the *boutonnière*. Desault was a notable exception; to him cystotomy was so rarely indicated that in the *Hôtel Dieu* he found occasion to use it only once since the introduction of the catheter by a skilled surgeon must almost always be successful. They punctured the bladder from the perineum, above the pubes or through the rectum. The first, and at the same time the oldest method, was the most uncertain and the most dangerous and was almost entirely discarded. Only B. Bell advocated this operation, which Theden very often saw result fatally. The puncture above the pubes, probably first made by Méry in 1701, was regarded as easy and not very painful. It was almost impossible in that way to miss the bladder and injure an important part. The danger that the bladder in its evacuation would draw back from the tube of the trocar and an infiltration of urine follow, was obviated by the use of the long, somewhat curved trocar of Frère Cosme. Otherwise inflammation soon entered the wound, whereupon the cicatrization of the bladder with the abdominal muscles was occasioned and its contraction prevented. After a few days an elastic tube could be inserted. This puncture was absolutely necessary in swelling of the prostate, but was contraindicated in case of very fleshy persons. Recommended by Sharp and Heister it was regarded as the best method (Turner and Brown) even when the puncture through the rectum had been established. This was a discovery of Flurant. This operation, simple of itself, possessed the single danger of injury to the seminal vesicles. These were avoided, however, if the curved trocar devised by Flurant was inserted as deeply as possible into the rectum and the bladder perforated as high as possible and exactly in the middle. The tube which was left in the rectum naturally caused discomfort. In affections of the rectum and

the prostate bladder puncture was just as little possible as for women, in whose case the vagina was punctured with success (Bell). Flurant's method was made known by Pouteau (1750), was introduced into Germany chiefly by Schmucker, and much later in England by Reid (1778). Reid indeed preferred it to the use of the catheter, whose unskilful application was much more dangerous. Soon it displaced the puncture above the pubes; Richter even called it the best, most comfortable, easiest and safest method. J. Hunter, Desault and Theden recommended it, while B. Bell rejected it entirely.

Desault traced *hematuria* either to the kidneys (stones and unnatural relaxation of the renal vessels) or to diseases of the bladder (varicose swelling of the vessels, fungous excrescences, stones and wounds). The inhabitants of tropical countries were especially liable to hematuria; Desault cured many soldiers who came back from the East Indies, by the use of the elastic catheter.

Renal calculi became the subject of surgical treatment as soon as the abscess produced by them formed an undulating tumor in the lumbar region. This constituted the indication for *nephrotomy*, i. e., for the opening of the abscess and the extraction of the stone. This operation had already been recommended in a work of Hippocrates. Therein is stated that if pus has been formed in the kidneys, this must be removed with the gravel; then there was hope of saving the patient. If the diagnosis was certain an opening not too small must be made as early as possible, the finger introduced and the stone, if free, removed; fixed stones were allowed to be released by nature and for that purpose the hole was kept open by means of a pledget. The operation was first performed as it appears, by Marchettis (1696) on an English consul, for an abscess in the lumbar region, and it was warmly advocated by Rousset and Riotan, and then by Heister. He supported his position upon the fact that "renal wounds, if they are inflicted from behind and do not enter into the ventral cavity, are not always to be regarded as fatal." Later, Hevin, Troja and Earle commended it and C. C. von Siebold exclaimed emphatically: "When will the men who are so courageous and fortunate in the preservation of mankind in the exercise of the arts of surgery, again address themselves to the renal incision in order to remove the deadly stones from the kidneys as well as from the bladder?" It was a question whether the operation should also be undertaken in case an abscess was not present. Although one successful result was known ("Philosoph. transact.," 1696, art. ii, p. 188), they advised against it on account of the uncertain diagnosis, and because the soft parts lie too close, moreover an excessive hemorrhage was to be feared; it was difficult to find the stone and dangerous to loosen it with the knife if it was wedged in tightly (Richter, B. Bell). Only Lafitte considered nephrotomy also indicated, when there being no abscess, the stone could be recognized as a tumor by its hardness. *The extirpation of the kidneys* became a subject of discussion through an observation of the Englishman Fearon ("Med. communic.," i, London, 1784). He diagnosed a large tumor of the kidneys and had an inclination to extirpate it; the patient died. Then he performed the operation on the cadaver; without injuring the peritoneum he took out a kidney weighing two pounds and said that one could extirpate a diseased kidney if it forms a tumor on the outside. But Richter objected

that in case of a living body hemorrhage and other evil consequences must be considered, and one must also have assurance that the other kidney is healthy and able to secrete the urine.

The study of diseases of the testicles languished; they were often confused. Monro, Sharp, Garengot, and Pott, in particular, won credit for themselves in respect to these ailments. Surgeons showed an active interest in hydrocele, the treatment of which was enriched by many improvements. Only little by little were clear views obtained as to the seat of the infiltration of water. Garengot distinguished accurately infiltration into the spermatic cord from that into the vaginal tunic, while Sharp rejected the finer distinctions as to its seat and only distinguished hydrocele of the tunica vaginalis from hydropsy of the scrotum. According to Heister, the water lay for the most part in the tunica vaginalis, sometimes in the proc. peritonei, and exuded from the "ruptured lymphatic vessels (vasa lymphatica)." Congenital hydrocele was also known to him. With anatomic accuracy, Pott distinguished the various seats of the disease, described hydr. of the tunica vag., hydr. cystica and that in the tunica vaginalis of the spermatic cord. To these three kinds Richter added hydrops scroti and infiltration of water into a hernial sac.

For *hydrocele* of the tunica vaginalis, the oval form, fluctuation, position of the testicle behind the tumor, etc., served for diagnosis; the transparency seemed uncertain, since the scrotum might be very thick and the water turbid (Sharp). A contusion, induration and inflammation of the testicle, cold and syphilis were considered the most frequent causes. A dispersion of the tumor by means of medication offered a prospect of success only in the case of children. In such cases cures were accomplished by purgatives and emetics, poultices of an infusion of rosemary or sage in wine or brandy, the application of compresses which were wet with vinegar, or a solution of sal ammoniac in alcohol. With the last mentioned remedy the English military surgeon, Keate (1788) would for the most part dispense with the operation. In the case of new-born children, Monro applied a piece of flannel saturated with smoke of benzoin, and Heister had a healthy person chew a piece of nutmeg and then blow frequently upon the scrotum. The operation was palliative or radical. While for Sharp, the former always sufficed, and the radical operation appeared too dangerous, Richter preferred the palliative operation only in very large hydrocele, in case of doubt as to whether the testicle was diseased and in complications with other diseases of the testicles. If one had assured himself of the position of the testicle, a lancet, or better, a trocar was inserted below and in front, and the water allowed to escape, but not all at once. The lancet should have the preference in case of slight infiltration of water in complications with hernia and sarcocele. In such cases they severed the skin and then inserted the trocar into the exposed tunica vaginalis (B. Bell). J. L. Petit first called attention to the evil consequences of perforating a blood vessel in the spermatic cord.

In the radical operation it was necessary to destroy the cavity of the tunica vaginalis, since they either cut this out or induced inflammation in it in order to bring about an adhesion with the testicle. To that end there were a number of methods, of which Richter asserted that each deserved preference in certain cases, no one of them in all cases. For most cases of

hydrocele the incision was regarded as the best method. The tunica vaginalis was split throughout its whole length to the base of the scrotum (Monro) and a pledget, or a piece of fine linen spread with digestive salve, introduced. Filling with lint (Lassus) occasioned too great pain. Although the incision was decried from many sides as dangerous (Wiseman, Cheselden and Earle), which Pott, however, denied, and although suppuration of the testicle (Sharp) and a fatal result (Acrel and Monro) were noted, still these methods were for the most part in use at the end of the century. If critical conditions ensued Richter laid the blame on the surgeon; he and also B. Bell defended the incision against all other methods. If the tunica vaginalis was unnaturally thick and hard, its extirpation, already known to the ancients, had given good results. Douglas reintroduced it (1755); Saviard, White, Gooch and Louis followed him. Not infrequently the results in this way were less serious than in a simple splitting of the tunica vaginalis (Bertrandi). A third method, taken up by Warner (1774) and Theden, was the insertion of a tent, which was daily renewed and allowed to remain until sufficient inflammation was induced. It was unsafe and irritated the testicles more than the tunica vaginalis. The injection of irritating fluids found many advocates. It appears to have been first done by the Marseilles surgeon Lambert (*Euvr. chir.* 3. Aug. 1677); he used a solution of sublimate in lime water. The method appears to have been long forgotten until Monro appears to have reintroduced it and first injected alcohol and afterward wine. Alcohol was a deceptive remedy; when Sharp had injected an ounce of it an abscess on the scrotum resulted. Sabatier cautioned against it and used the weaker red wine. Solutions of nitrate of silver, alum, vitriol, sugar of lead, lime water and simple cold water were also used. The liquid was allowed to flow out again immediately, and care was taken that nothing remained; the quantity depended upon the size of the tumor. Voices were raised for and against injections. Richter considered them not safe enough, since B. Bell had reported one failure in nine cases, and brought forward as a disadvantage, that sometimes very severe inflammation and suppuration resulted; he limited them, therefore, to simple, slight hydrocele. Many experiments were made in France and their results reported; fewer, in England. Earle (1791) defended this method, and said in its favor that it induced only very slight inflammation which never led to suppuration, hence could be used for every constitution and at all ages. It also has neither obstacles nor dangers, and in case of relapse can be immediately repeated. He used port wine with a decoction of rose leaves (2 to 1) and described twenty-seven cases. He successfully treated large nodules and mucous sacs at the patella with the same injections. Desault also preferred the injection for congenital hydrocele. By means of a cushion he lifted up the communication between the abdominal cavity and the tunica vaginalis, punctured it and injected red wine, and had the patient wear a truss that the peritoneum might not enter the lacerated tunica vaginalis. Hydrocele, sometimes also hernia, which was usually complicated with it, was radically cured by the occurrence of adhesions in the cavity. Zenker appears to have introduced the Earle injections into Germany; at least he made them, with success, of equal parts of water and medoc, in the Berlin Charité in January, 1795. The method was

later forgotten there, for Rust and Gräfe operated with the incision. Pott valued and preferred to the incision, as one of the most excellent remedies, the seton, which Lanfranci first used and Paré among others had recommended. He used it many years with successful results, at first in the form of a wick of cotton, later of sewing silk, which irritated less. Pott asserted that by this method the tunica vag., simply affected with inflammation, adhered to the testicles, but suppuration never ensued. Even in his lifetime the general voice was raised against the seton; Sabatier first interested himself in it again. The technique of the operation was considered too inconvenient and excessive suppurations and aggravated conditions were observed to follow (B. Bell, Earle and Richter). Cauterization, by which the ancients opened the tunica vaginalis in its entire length, was introduced through Else, a surgeon in the Thomas Hospital in London (1770) and Dussaussoy in Lyons (1787), but only for the purpose of inflaming the tunica vaginalis. A paste of lapis causticus was selected and with it a scab the size of a louis d'or was made, opium also being applied (Acrel). The pain and subsequent suppuration restrained many surgeons from cauterization.

Under "cystic hydrocele" (*hydr. cystica*) was understood the tumor which occurs especially in children and consists of an unnatural sac in the cellular tissue of the scrotum, for the most part in the region of the middle of the spermatic cord. Below and above it the latter could be freely felt. Resolvents did not suffice, but a simple puncture or, in adults, the splitting and excision of the sac led to a cure. From this species, "hydrocele of the tunica vaginalis of the spermatic cord" was distinguished. In the latter the water collected in the cellular tissue which immediately surrounds the spermatic cord; wherefore the tumor was also called edema of the spermatic cord. This rarest form could either attack only the lower part of the spermatic cord and extend as far as the abdominal ring, or it entirely filled with water the cellular tissue which passes with the spermatic cord through the abdominal ring. They opened the tumor.

Diseases of the testicles were so little the subject of anatomic investigations that under *hematocele*, which name originated with Heister, was understood an infusion of blood into the cellular tissue of the scrotum and the tunica vaginalis, as well as into the substance of the testicle. The second form developed after the palliative operation for the common hydrocele if a large blood vessel was punctured, or after a contusion. They sought to resolve small tumors by purgatives, solutions of sal ammoniac and by external pressure by means of a suspensory; larger ones were lanced or cut out. In the third form, which Pott discovered, the testicle was swollen and so soft that it could be pressed flat without pain; thin chocolate-colored blood was exuded into its substance. Castration was here the only remedy, although for years the swelling often occasioned only slight inconvenience.

Under *sarcocele* was understood an induration and swelling of the testicle, and all neoplasms of the same were classified in the following manner: If the tumor was painless, it was regarded as benign scirrhus; if painful, as malignant and latent cancer; if ulcerated, as open cancer; sarcocele arose after contusion from venereal, scrofulous and gouty causes, among others. In regard to its treatment, J. L. Petit was the first who demonstrated the possibility of a cure of a syphi-

littic testicle tumor by anti-syphilitic remedies. Naturally they then sought to contend against other dyscrasias by corresponding medication. Yet *castration* remained the surest remedy, to Sharp one of the saddest operations and one which was allowed only in scirrhus and cancer of the testicle, which was very liable to relapse. He postponed the operation until the tumor threatened to become malignant, while most surgeons would castrate as soon as possible after pains arose, since one could never know whether or how long the swelling would remain benign. Only when the pain was no longer local and the spermatic cord and inguinal glands were also indurated they advised against the operation. Volumes have been written on the technique of castration, since there were few operations which in the last century were so variously modified. As a rule a large longitudinal incision was made from the abdominal ring to the base of the scrotum, or only a small incision above the spermatic cord, in order to expose the latter, and the incision was further enlarged (le Dran and Mourro.) Then the spermatic cord was isolated from the cellular tissue, bound and severed, whereupon finally the testicle was removed. The oldest method was to bind the entire spermatic cord. In Heister's time they applied a simple or double ligature around the vasa spermatica close to the abdomen before they cut off the testicle. A few surgeons loosened the testicle from the scrotum after applying the ligature, but waited a few days until it began to putrefy in order to be able to separate it so much the more safely. The stricture of the entire spermatic cord had a few successful results (Sharp, Morand, Acrel, Pott and Schmucker; Mursiuna thus performed sixty-four castrations and observed trismus arise only twice). But severe pains (Bell) were observed and trismus with fatal results (Morand), convulsions (Bilguer), and epilepsy (Theden). Views upon this kind of operation were widely diverse. J. L. Petit rejected the ligature of the spermatic cord entirely, since the hemorrhage from the small arteries was only slight, and preferred the isolated torsion of the vessel, and le Dran and White did not bind the spermatic cord but only rolled it between the fingers. A few would draw the thread only tight enough to close the artery (Bell and Lassus); others bound the artery alone (Monro, Cheselden, Z. Vogel and C. C. von Siebold). Richter laid down the following rule: If the spermatic cord must be cut off close to the abdominal ring one should bind the whole mass with a thread not too thick; if it is to be separated far below the abdominal ring one should endeavor to bind the artery alone. It was always advisable to cut the spermatic cord as far down as possible because it contracted so much. Since many accidents might arise from the straining of the spermatic cord importance was attached to freeing it as far as possible from the surrounding parts so that it could contract unhindered (Maréchal). Most surgeons arrested the hemorrhage by ligature, while Theden recommended the tampon, on account of epileptic attacks. Of course in case of very small arteries it was often possible to stop the blood by continued finger pressure, but it might be a question of a vessel of the size of the art. brachialis (Sharp), and a dangerous hemorrhage might arise after compression alone (Pott). They advised attempting a healing by *prima intentio*. A radical method of castration, as that of the Austrian surgeon Zeller, was not to be thought of. Proceeding from the idea that the extirpation of the testicle at

the base of the scrotum accomplished nothing, he seized the diseased part along with the testicle, drew them backward and severed sac and testicle at once; the hemorrhage was stopped with ice-cold water.

In *varicocele* they distinguished *cirsocele* as varicosity of the spermatic cord and testicle, from *varicocele*, as an enlargement of the veins of the scrotum. Richter believed that the tumor was not based upon a varicose swelling of the vessels of the spermatic cord alone, but that the spermatic vessels in the epididymis and the testicle also swelled. The feeling as of a bunch of angleworms could not be derived from distended veins, and the eventual atrophy of the testicle could only be explained in that way. J. L. Petit said that a predisposition to the development of varicocele was to be found in the mechanical condition, that the vessels of the spermatic cord ran upward over the os pubis as the cable of a well across the roll, and that the testicle works as the bucket of the well. They named as causes, a torpidity of the spermatic vessels (in onanism), an increased afflux of liquids (in suppression of coitus), contusion, obstructed reflux of the fluids (bad truss). The disease could never be entirely removed, but an exacerbation could be prevented. The continuous wearing of a suspensory, cold lotions, the application of alum solutions and of naphtha served to that end. In case of very severe pain, or threatened rupture, one should castrate (Gooch). The stricture of the veins, according to Celsus, as well as the puncture of the vessel with a lancette, according to Heister, and the extirpation of the varicose veins, were regarded as too dangerous. In case of healthy testicles, Pott rejected every operation. Observations as to cryptorchism were made as early as the seventeenth century. Petri de Marchettis¹ found in a child one testicle "near the pudendum," the other in the scrotum, and advised against any treatment, when a colleague would bring the supposed tumor to suppuration ("Chir. Obs.," lviij, Uebers., Nürnberg, 1673). Felix Plater described three cases and the confusion with hernia ("Obs. Sel. Obs.," 47, 1680). Pott offered new observations. He was aware that it was subject to all the diseases of the testicles, and that it might be regarded as a rupture, and could become inflamed through pressure of a truss, and from an injury. He observed it grew scirrhous and cancerous, and also described the successful extirpation of a cancer. Plenck likewise called attention to the distinction between inguinal hernia and bubo, and taught that cryptorchism with defective treatment might inflame, suppurate, harden and develop into inflammation or cancer.

Richter considered the operation for *phimosis* as inadvisable, in case urination was not obstructed "until the patient wished to fit himself to undertake coition, for which purpose, as C. C. von Siebold relates, young Frenchmen had the frenulum cut. A few surgeons preferred circumcision to a simple splitting, because after the latter misformed flaps remained obstructing coition (Richter); others preferred the simple incision and limited circumcision to a thick and hard prepuce (Sharp). The latter was made with bistoury or shears, the longitudinal section with a bistouri caché, with which the strongly contracted foreskin was perforated above in the middle and from

¹ This surgeon is today so little known that several of our recent handbooks relate the story of how Marchettis had extracted a pig's tail which Göttingen students had stuck into the anus of a Jewish girl. Marchettis died in 1673 and the University of Göttingen was founded in 1734.

within outward, and was cut through from the back, forward. Then the flaps at the sides of the incision were cut off, since they often occasion much trouble. At each bandaging a pledget was pushed into the upper corner of the incision; it was not sutured. A number of bistouries with the most widely differing pointed covers were constructed for this operation (Petit, B. Bell, Bertrandi, Lotta and others). The incision was also made at the side of the gland (B. Bell and Arnemann) or only the inner layer of the foreskin was cut, as almost the only place of contraction (Foot).

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Ophthalmological and Otological Society.

Regular meeting held Nov. 9, 1897, in the Stewart Building.

Dr. MONTGOMERY in the chair.

There were twenty six members and visitors in attendance. The minutes of the last meeting were read and approved. Drs. A. E. Bulson, Jr., of Fort Wayne, Ind.; E. A. Lawbaugh of Chicago, and J. B. Taylor of Bloomington, Ill., were elected members.

Dr. PIERCE opened the discussion on "Chronic Suppurative Otitis Media." He said that a proper comprehension of the factors involved in the treatment of chronic suppuration in the middle ear may best be arrived at by briefly considering: 1, the pathologic processes which induce suppuration in the tympanic cavity, comprising the micro-organisms involved; 2, routes of invasion, and 3, the conditions which prevent their escape or destruction. These three points were discussed seriatim. In considering the treatment he had come to believe from experience that many cases of catarrhal inflammation assume a suppurative or chronic form because of ill-advised treatment. One of the most prevalent errors in this regard is the empiric and illogic use of ear drops, douches and inflations. The author showed that this was bad treatment. The first condition to be met in chronic, as well as acute otitis media, whether suppurative or catarrhal in form, is drainage. There is no other factor which tends to perpetuate a suppurative ear disease so frequently as lack of drainage or retention of discharge. At his clinics he rarely uses injections. The ears are cleansed by carefully swabbing away secretion by means of sterilized cotton pledgets. These pledgets are kept constantly on hand. The external auditory canal is then packed with a strip of sterilized gauze, care being taken that it barely touches the membrane.

With reference to douching the author said there are a few cases which demand irrigation, and in these the ear is cleansed through the Eustachian tube whenever possible. When the affection is bilateral he uses Greuber's method. A syringe with a blunt point holding two ounces is introduced into the nostril. The other nostril is closed by the thumb as in politization. The patient is told to blow out the cheeks forcibly when the contents of the syringe is forcibly ejected. In this way the solution is forced through the Eustachian tube into the middle ear through the perforations into the external auditory canal.

Surgical treatment.—When the discharge continues after a month's treatment by the method described, the author resorts to operative interference, providing there is no indication of polypous formation or caries. In the case of a polypus being present he snares it away immediately, or in the case of opposition to surgical interference on the part of the patient, he reduces it by means of sesquichlorid of iron or alcohol. In his hands syringing of the attic by means of Hartmann's canula has proven unsatisfactory in almost all cases.

The author then touched on a few practical points that had been impressed upon him by his own experience. As regards narcosis, chloroform or a general anesthetic should always be used in those cases where any considerable amount of the membrane remains, for here the pain is usually intense during the operation, and hemorrhage from the granulation is very likely to delay manipulation. Cocain may be relied on in those cases where the tympanic membrane is largely destroyed and where granulation tissue is nearly altogether absent. The attic can be best cleaned by the attic scoop. The after treatment should be the same as that pursued before operation, namely, packing with gauze drains. He had seen cases that

have run along for twelve years or more in which suppuration ceased in two months after the operation.

Dr. EDWARD T. DICKERMAN referred to the varying susceptibility of different patients to middle ear disease, and attached importance to the condition of the nasopharynx in these cases. He had found that in cases where the Eustachian tube was blocked by nasal growths that ear disease was far more common. Regarding treatment he agreed with Dr. Pierce that the dry method was by far the best, and he believed that acute cases would never become chronic if properly treated. The bone which most often necroses is the incus, because the blood supply is entirely from one small artery which is easily occluded, any slight pressure from swelling being sufficient. In these cases of necrosis a thorough curetting is absolutely essential and due care must be had for the facial nerve, which is easily injured by instruments or any escharotics. He had found that the improvement in hearing in most of the cases was marked.

Dr. HENRY GRADLE—A fair experience has shown me that the gauze drainage advocated by Dr. Pierce is the speediest treatment at present known in acute inflammation of the middle ear, but I have never used it as yet in the chronic form. In discussing the treatment of chronic suppuration of the middle ear, I wish to emphasize certain principles which I fear are not yet appreciated by all practitioners. In general surgery it is well known that the tissues will invariably recover from pyogenic infection if the pus can escape freely, and there are no untoward conditions present, as for instance, foreign bodies. The same is true of inflammation of the middle ear. For anatomic reasons there is, however, much liability to the damming up of the pus with consequent persistence of suppuration. The reasons are partly obliquity of the meatus, partly the complex architecture of the tympanic cavity, the liability to the formation of occluded crevices by swelling of the mucous membrane or granulation tissue, and particularly the partial occlusion of the attic by adhesions and newly formed bands of tissue. All these conditions interfere with free drainage of the pus, and thereby favor secondary infection with putrefactive bacteria from the meatus. Inspissated pus moreover acts as a foreign body and thus maintains continued suppuration.

A valuable sign of retention of pus in the cavities of the middle ear is its odor. Freely escaping pus has no fetid smell, while a foul odor indicates imperfect drainage. We can make use of this important criterion to test the efficacy of treatment. On the basis of much observation of such cases, I can state emphatically that any treatment which does not remove the odor will never lead to a cure of chronic purulent otitis, and that, conversely, whenever the odor has been removed the tendency to recovery can be at once observed. A small number of cases may not entirely heal under the treatment which removes the odor, but this is a rare exception. On the other hand, the first principle stated has no exception whatsoever.

My treatment always begins with the free use of the syringe. A fine nozzle protected by a bit of soft drainage tube must be carried far into the meatus. Thorough syringing alone cures many cases. I can say this on the basis of some cures accomplished by syringing followed by the experimental use of various powers like iodoform, which I since learned to be absolutely inert. But syringing will not cure all cases, nor is it the speediest form of treatment when employed alone. All uncomplicated cases of purulent otitis will heal under the use of boric acid lightly insufflated after thorough cleansing. In a small percentage of instances a single insufflation has resulted in a permanent cure. If the cure is delayed there are complicating conditions present which we must inquire into, and these do not yield any more readily to the various substitutes recommended for boric acid. What we wish to accomplish by insufflation is to put into the ear a depot of a non irritating antiseptic which checks bacterial activity on the surface of the tissues. Boric acid answers these requirements so fully that I can see no reason for any search for substitutes for it. The addition of any antiseptic fluid to the water used for syringing appears unnecessary to any one familiar with surgical pathology, and many trials in former years have convinced me of the utter uselessness of all fluid antiseptics (including peroxid of hydrogen). Insufflation through the Eustachian tube I formerly used as a routine measure, but I have failed to see the least delay from its omission.

If these measures do not remove the odor after one or two treatments, other means must be adopted. Irrigation through the Eustachian canal has not proved of any use in my hands for the purpose of removing pent-up secretion of inspissated pus. I have learned to regard, however, as very valuable, irrigation of the tympanic cavity and attic through the intra-tympanic canula. Hartmann's rubber tube is too thick. I use a silver tube, closed at the end, with lateral eye attached to a ten centimeter piston syringe. Its efficacy is shown in

suitable cases by the appearance of grumous pus collections in the basin, and the disappearance of the odor. It is often painful to the patient, but I have never seen any harm done by its use. Intolerance of the patient may require a repetition of its use at different sittings until all odor is removed. In some instances, in which no complicating lesions existed, but where the intratympanic canula failed to dislodge the retained pus, I have made use of fluids capable of penetrating better into the small crevices than water on account of their lowered surface tension. I use first a solution of salicylic acid in alcohol and ether, and follow this by carbolated glycerin 1 to 10. A number of times my reasons for the employment of these solutions were justified by the subsequent disappearance of the odor and the progress of the case. I have also made attempts to dissolve carious bone by baths of hydrochloric acid (5 per cent.), and to digest obstructing granulation tissue by acid pepsin solutions, but am not convinced that I have ever accomplished anything thereby. If these modes of treatment fail to remove the odor, we must attack surgically those conditions which interfere. Polypi must be removed, although small ones may sometimes disappear by absorption under such treatment without delaying the cure. Visible granulation tissue is to be curetted. Carious bone must be cleansed by the curette of adherent fragments of tissue; but when cleaned it does not interfere with recovery, as I have learned repeatedly. Small openings in the membrana tympani, or in Shrapnell's membrane, may be enlarged, although I have but rarely seen any benefit from this procedure. When persistence of the odor indicates the inefficiency of the treatment, I attempt to clear out, with the snare and curette, the entire tympanic cavity, removing as much as possible of the ossicles, so as to expose the attic freely. I have, however, not concluded to do a simple Stacke operation, for the reason that Stacke himself found that in most cases requiring this operation, the mastoid also is involved. Whenever, therefore, I find that I can accomplish nothing by the minor surgical measures, I perform the Zaufal operation, and convert the antrum, tympanic cavity, attic and meatus into one cavity. Of all complications, the most important is the existence of cholesteatoma. If with this condition, the odor can not be removed, a radical operation is required. If the deodorization can be accomplished the cases generally heal, and may stay cured for months or years, but relapses rarely fail to set in.

As a rule, otorrhea diminishes steadily until cured, after the odor has been removed. There are, however, a few rare cases where many months may be required for this result. Generally the treatment will not extend over a longer period than four to six weeks at most.

There are some cases in which no odor is present when first seen and which still prove very rebellious to treatment. They are characterized by a very profuse, stringy, muco-purulent secretion which presumably comes from the mastoid antrum. In instances of this kind in which there are no indications for naso-pharyngeal treatment, I have often found it possible to influence the secretion very markedly by the use of tannin dissolved in glycerin, 1 in 4, retained in the ear for hours. Repeated trials have shown me the efficacy of this treatment under these conditions, but it is not infallible. Some of these cases with profuse, stringy secretion occur in children with a similar profuse chronic purulent rhinitis. This disease has been described by Bosworth as a special type occurring in children, and I can confirm his description fully, but must differ radically from him regarding its ultimate outcome. He considers it the first stage of ozena. I can not admit this at all, as I have watched some of these children for months, partly after the efficacious treatment, partly after treatment insufficient on account of frequent interruptions. Moreover, a few cases of ozena which I and others have been able to catch in their incipency began in an entirely different manner. This chronic purulent rhinitis of children can be cured by the persistent use of the nasal douche kept up for many months. The same irrigation extended into the Eustachian tube, will also cure the corresponding form of middle ear disease. When both ears are involved it is easy to use the Politzer bag, filled with saline solution, instead of air. When the disease is one-sided the more cumbersome Eustachian catheter must be employed. With such irrigation boric acid insufflations must be combined.

It may not be amiss to add that hypertrophy of the pharyngeal tonsil is not only a frequent cause of inflammation of the middle ear, but accounts also for many relapses observed in childhood, and that in every case of chronic otitic suppuration we must attempt to restore a normal condition of the nose and pharynx.

Dr. TILLEY is a firm believer in syringing in these cases and thought it of more value than the dry method of treatment. He uses a bulb syringe similar to the one used by dentists, and

injects the fluid into the tympanic cavity. He finds a solution of carbonate of soda most valuable for syringing. He considers constitutional measures of the greatest importance and uses the solid iodid of iron and cod liver oil in nearly all his cases. The nasal condition is also carefully looked after.

Dr. WHEELLOCK agreed with Dr. Gradle that the odor of the discharge is a good index to the condition of the ear. He syringes most of his cases with peroxid of hydrogen, allowing it to remain in the ear for some minutes. Where granulations are present he finds that they can be most comfortably removed with absolute alcohol. He has been recently trying a 0.5 per cent. solution of formalin instead of the peroxid, and finds it very satisfactory. It seems to have a more penetrating effect than any other solution. Patients are instructed to syringe the ear with at least two quarts of hot water, at home, by means of a fountain syringe held a few inches above the level of the head.

Dr. COLBURN uses peroxid quite frequently, but called attention to the dangers of using it in cases with perforations because of the pressure exerted by the gas in the middle ear.

Dr. COLEMAN also uses peroxid freely. For some time recently he has been using the Politzer method of inflation in combination with cleansing the ear and considers it very satisfactory. He does not think there is any danger of reinfecting the ear from such treatment. When granulations are present he destroys them with chromic acid.

C. P. PINCKARD, M.D., *Secretary.*

The Eighth Italian Congress of Internal Medicine

Naples, October 20 to 24,

was opened by Prof. G. Bacelli, who urged further work in the line of the intravenous administration of heroic medicines, "first practiced in Italy, but now finding adherents all over Europe and in far America." Quinin was the first thus introduced into the system, and many a patient in the pre-agonic stage was saved by it. Then bichlorid of mercury was tried and afforded marvelous results, not only in syphilis of the brain and spine, but even in the gravest disturbances from pathogenic micro-organisms and their toxic products, especially influenza. Then iron was attempted and other substances will certainly follow, although the endovenous method is obviously for exceptional use.

Prof. E. Maragliano described the important information to be learned with the Roentgen ray in regard to the thoracic organs, especially in incipient disease.

In his address on "Leukemia," Professor De Renzi went over much of the ground covered by the work of the Chicago Pathological Society (*vide JOURNAL*, Vol. XXIV, Nos. 4 and 25; also "Leucocytosis," Vol. XXIX, No. 10, and editorial in Vol. XXVIII, No. 20). He stated in conclusion that leukemia is not a morbid entity, but a symptom connected with physiologic and pathologic leucocytosis. Two factors are necessary, the inciting agent and a predisposition on the part of the organism. Given this predisposition to the exaggerated production of leucocytes, several micro organisms are capable of acting as the determining factor, hence the variety of types of leukemia, but an extremely susceptible nervous organization is common to all. Pasteur and others have found the staph. pyog. aur. and alb. and the bac. coli in leukemia, but Pane in his recent extensive research failed to discover any micro organism, even with inoculations of dogs and monkeys. De Renzi has observed typical anemia infantum pseudoleukemica in adults; it is an actual scourge at Barano d'Ischia. At present much importance is attributed to the neutrophile mononuclear leucocytes, but this importance is still dubious. Pane considers the granules of the polynuclear leucocytes physiologic, as an aqueous instead of a glycerin solution of eosin renders them acidophile. The existence of intermediate forms between the eosinophile and neutrophile granules precludes any deductions from them, and it is better to depend for the diagnosis upon the permanent multiplication of the white corpuscles and the hyperplasia of the hematopoietic organs. The theory of increased activity on the part of the cytogenic tissue (Virchow, Bizzozero), is confirmed by this hyperplasia of the hematopoietic organs, also by the abundant destruction of the leucocytes in the organic transformations, especially since Hurbaczewsky has succeeded in differentiating the albumin from the nuclein transformations, the first producing oxyproteic acid and urea, the latter uric acid. Recze found an increase of five to eight times as much as normal in his cases, and when uric acid could not be found, it was substituted by xanthin, hypoxanthin, Rovidá's hyaline substance and Lilienfeld's nucleo. The erythrocytes are affected in leukemia, showing degeneration either as poiki-

locytosis or in the endoglobular changes described by Maragliano. Fever may or may not be present; it has no special characteristics. There is no prompt and radical cure for leukemia, but arsenic may prove beneficial; organotherapy promises still better results, and possibly Tesla's currents, which promote to a remarkable extent the organic oxidations without increasing the consumption of albumin.

Marchiafava considers leukemia and pseudoleukemia distinct affections, the latter a secondary infection favored by profound anemia. In the ganglion and intestinal variety the spontaneous increasing and decreasing in size of the ganglion tumefactions is still an inexplicable phenomenon. The internal ganglia may be the first affected; in the thorax it is the mediastinal and peribronchial ganglia, the process extending to the lungs or pleura. In the abdomen it is the mesenteric or retroperitoneal, or both. When the lymphoma invades the walls aneurysmatic dilatations are noted, while cancer and tuberculosis produce stenosis. The importance of the splenic tumefaction in splenic anemia, which must not be confounded with splenic pseudoleukemia, is evidenced by the complete recovery after extirpation of the spleen, in the early stages. Arsenic is still the most effective treatment of pseudoleukemia. Surgical treatment of the ganglion tumors is not to be advised. Bozzolo reported a case in which these tumors disappeared spontaneously, but reappeared ten years later, followed by leukemia. He remarked that leukemia of the skin is characterized by papulous nodules, which are often the first symptom of leukemia. He recommends subcutaneous injections of sodium arseniate in large doses. Pane communicated the results of the inoculation of rabbits with strong doses of pneumococci after immunization. He found intense hyperplasia in the bone marrow and in the spleen. Before death there was a great preponderance of lymphocytes and the white corpuscles were much more numerous than normal. He added that these experiences might prove valuable in differentiating acute leukemia from the leucocytosis encountered in certain infectious diseases. De Semo reported extremely favorable results from calomel in very small doses in twenty cases of pseudoleukemia or infantile splenic anemia.

The address on "Cardiac Neuroses" was by Silva of Pavia, who remarked that we no longer include angina pectoris and Basedow's disease in this list. He explains the etiology of paroxysmal tachycardia by studying the connection between the clinical manifestations and the physiologic data, the former bearing a striking resemblance to the attacks of tachycardia that affect workmen or mountain climbers making unwonted efforts, due to transient neurosis of the pneumogastric. We know that weak excitation of the pneumogastric, when it does not calm the tachycardia, exerts an antitonic action upon the heart and also, on the other hand, that slight excitation of the sympathetic increases its accelerating function. According to Murri, the force of the systole is in direct proportion to the amount of blood contained in the cardiac cavities, and thus, in tachycardia, when the cardiac tonus is diminished and the heart dilated, we have an element which easily explains the increase in the number of the cardiac contractions. The pneumogastric begins the attack; after this the poisons produced by the excessive activity of the heart, prolong it. The facts that compression of the pneumogastric at the neck arrests the tachycardia, and that digitalis is extremely efficient in this affection, demonstrate the correctness of this theory, which attributes the clinical phenomena to the influence of the myocardium and the pneumogastric, especially as we know that the chief effect of digitalis is precisely this increased tonicity of the cardiac fibers, which is ascribed by many to excitation of the pneumogastric. The abrupt termination of the attack is owing to the excitation of the intracardiac ganglia and the cardiac terminations of the pneumogastric, by the cardiac dilation and stasis, which stimulate the pneumogastric center by reflex action, and this in turn brings the heart back to its normal condition. Cardarelli's fine monograph on bradycardia attributes the affection to arterial lesions. Paroxysmal bradycardia may prove fatal during the first or later attack, but cases have been known to last fifteen years, although the average is three and a half. The treatment for cardiac neuroses is the same as for others: Hydrotherapy, then massage, electro- and climato-therapy. He concluded with the remark that the myocardium is always involved in purely nervous cardiac troubles, as there is no longer any doubt in regard to the trophic action of the pneumogastric on the musculature of the heart. Calabrese confirmed the theory in regard to the part played by the pneumogastric in the evolution of bradycardia by the case of a young woman in good health until a sudden attack of syncope and epileptic symptoms, pulse 27, nausea, etc. Atropin raised the pulse to 60, but it grew slow again as soon as the atropin was suspended. Digitalis accentuated the symptoms. Tedeschi

sustained Kelly's theory, which attributes paroxysmal tachycardia to disturbed nutrition on the part of the neurone; the connection between the terminal ramifications being suspended, the vagus loses its tonic action upon the heart and tachycardia appears; it disappears whenever the cellular nutrition is regulated again. Gay remarked that in certain cases the tachycardia is one commencement of angina pectoris, and it requires the suppression of the cause (tea, coffee, tobacco) and prolonged medication, strychnin alternating with nitroglycerin, milk diet, etc.

De Renzi has confirmed in diabetic patients the results attained by Kossel *in vitro* in regard to the production of carbohydrates when nuclein is treated with diluted acid. He administered nucleinic acid, nuclein and thymus in diabetics during the complete absence of glycosuria and in every case not only was the elimination of uric acid increased but the glycosuria reappeared, showing that nuclein must also be considered as a source of carbohydrates in the organism.

The beneficial effect of Tesla's currents was proclaimed not only in leukemia, but in various diseases due to torpid metabolism ("experimental results surprising"), uricemia with eczema, etc. Lucibelli announced that the amount of fats eliminated in the urine of eight patients decreased one-half under treatment with the Tesla current. Tedeschi called attention to the splenomegalia which he has observed as a pretubercular symptom, the first to appear, and denoting a rapid and severe tuberculous infection. His cases were all convicts in prison. He considers it the expression of the struggle going on in the organism to throw off the infection. As the conclusion of much research Pittarelli denies the existence of physiologic glycosuria. Boeri announced that experimental lesions of the vagus lowered the limit of the destruction of glucose in the organism (dogs) (from 4 to 6 grams per kilogram, ingested fasting, and 2 to 2.5 grams injected into the peritoneum), to 0.75 to 1 gram, with neuritis of the central stump. Similar results were obtained with ligature of the choleodochus but none with lesions as in those without. The decrease in the limit can not be due to modifications in the general metabolism, as it is only produced by lesions of the vagus when the sugar is introduced through the peritoneum. With subcutaneous injections the limit remains unchanged (4 grams). He considers it probable that this function is exercised by the mediation of the liver, which fact is confirmed by the lowering of the limit with injections into an intestinal vein, while with injections of the jugular vein the limit does not vary.

A. Jovane stated that experimentation with dogs, and tests of sixty small children, necropsies of others, etc., had demonstrated that the prejudice in regard to the incompatibility of calomel with acids was unfounded. He administered the calomel with lemonade made with citric, tartaric, hydrochloric acid, orange juice, salty bouillon, chlorid of ammonium, etc., and there was not the slightest intolerance, and no lesions were found in the alimentary canal of moribund children thus treated, showing the non-formation of corrosive sublimate in the combination of calomel with the chlorids, acids and albumin. Massalongo classifies chronic arthropathy into infective, dyscrasic, toxic and nervous. Of all the theories advanced in regard to the etiology, he considers the reflex theory of Marinisco and Brissaud the most in harmony with the anatomic alterations. Chronic articular rheumatism he divides into four varieties, the infective, dystrophic, nervous and mixed. Various facts, among them the frequent discovery of peripheral neuritis both in the infective and nervous varieties, tend to establish the nervous origin of arthropathy. The most recent histologic investigations however point to the central rather than the peripheral system, and he believes that improved technique will in time discover in the spinal cord the primary cause of the affection. The exaggeration of the tendon reflexes is a special phenomenon of this infective group, which he has observed in 45 per cent. in the infective, 85 per cent. in the nervous and 60 per cent. in all. Zagari asserted that uric acid is not found in the blood and urine of patients with gouty arthropathy; that its administration does not produce the affection nor increase it if already existing; that there may be an excess of uric acid in the blood and urine from other morbid processes without the production of gouty arthropathy and that increasing the amount of uric acid by the administration of nuclein combined with compression and traumatism of the articulations does not lead to the evolution of the affection. He considers uric acid the companion of gouty processes, but the deposit of uric acid in the interior of the cellular nucleus after ligature of the ureter or an injection of uric acid, has convinced him that these processes depend upon some anomaly in the life of the cellular nucleus in some special tissue. As the metabolism is disturbed, the essential product of the metabolism of the nucleus, uric acid, is deposited in the

cell. Bacelli stated that the fundamental facts in chronic arthritis are the alterations in the white tissues and the disturbances in the lymphatic vessels. He mentioned as an early symptom "granulose pharyngitis," also an alteration in the periosteum over the anterior surface of the tibia, with edema, sometimes painful, with uratic deposits below. He has been using oxygen for a long while with fine results in the gouty forms, and also in fatty diabetes.

Maragliano announced that his precipitate of tuberculosis cultures contains both the proteins and the toxins, while Koch's new tuberculin is deficient in the former. It is also twenty times more potent than the product presented by Behring. He has established that the tuberculous organism produces antitoxin, itself, during the intermissions of the disease, which fact explains the clinic experience of spontaneous cure in some cases of tuberculosis. Many more cases would be cured if even a small amount of artificially produced antitoxin could be supplied from without to supplement the autoproduct. He concluded by reporting that forty-six patients cured two to three years ago with his serum, are still perfectly well, with no signs of recurrence. The serum was also endorsed by the experience of several other members.

Professor Queirolo ascribes much of the disturbance in typhoid fever to the imperfect digestion and consequent accumulation of decomposing matter in the alimentary tract. He avoids this by feeding his typhoid patients exclusively per rectum, as long as thirty days if necessary. He reports twenty-six patients thus fed, with remarkably favorable outcome, and no inconveniences. A careful study was made of the urine at the same time; the phenol and indican were much diminished or entirely absent during the rectal alimentation. He used Leube's nutritive enemas, four a day. The tolerance was perfect; opium was omitted after the first enema. Voit and Bauer have demonstrated that 20 grams of albumin can be absorbed by the rectum in a few hours. De Renzi warned against the danger of underfeeding the patient. He has been experimenting with subcutaneous alimentation, but finds it impracticable, as it is difficult to supply the proper amount of calories in this way. He added that the extension of the intestinal lesions would counter-indicate rectal feeding in some cases. Others approved of rectal feeding, especially in the case of children.

Germano confirmed the impossibility of the aerial transmission of the germs of cholera, typhus, and those of the bubonic plague. Menella reported prompt and certain improvement in tuberculosis limited to one lung, the pleura not involved, after gluteal injections of a solution of guaiacol, 30 grams; eucalyptol, 10 grams; and cod-liver oil, q. s. to make 100 c.c. A. Cantani also reported the favorable results of experimental research in regard to immunizing against influenza. He attributes his success to the fact that he used the exudations and emulsions of the organs of the infected animals.

Prof. N. Pauc's antipneumonia serum was endorsed by De Renzi, who has administered it in thirty extremely severe cases. All recovered except three; one with grave renal lesions, and the other two dying soon after being received at the clinic. He has also seen two otherwise inevitably fatal cases saved by the serum, which he announces is harmless, even in quite large doses. His mortality with other treatment averages 24 per cent.

The French Congress of Surgery.

As already mentioned, "Contusions of the Abdomen" was the subject of one of the addresses. The advantages of prompt laparotomy were extolled and numerous convincing instances related in which life had been saved by laparotomy immediately after the first nervous shock had passed away, the earlier the better. Other instances of a fatal termination showed the danger of waiting for the manifestation of serious symptoms, when intervention is too late. The patient should be kept warm in bed and watched for the slightest indication of trouble, such as lower temperature, especially of the tongue, faster or slower pulse, suspension or difficulty of urination, change in the voice, localization of the pain, cramps and dilatation of the pupil on the corresponding side when the blow was received on either side of the median line. If the pulse, rapid at first, grows slower while the patient is resting the case is seldom serious. It is important to differentiate between the nervous shock and the shock from hemorrhage. The circumstances of the traumatism are of great significance for the diagnosis. In Demon's experience a wooden rigidity of the abdominal walls always indicated a ruptured viscus. Moty remarked that in the less severe cases opium is the only resource, as ice sometimes entails grave complications, notably phlebitis. Doyen advocated Sneguireff's method of arresting sheet hemorrhages, such as occurs in wounds of the liver, by

directing a stream of steam upon the bleeding surface. It is also an excellent disinfectant. Michaux opens up largely, evacuates the blood with large aseptic sponges, examines the intestines systematically in warm sterile napkins and does not eviscerate except when fecal matter or debris is found. He leaves the abdomen largely open, localizing with iodoform gauze and injects serum into the veins at need, with peritoneal lavages with salted water and potassium permanganate. Doyen prefers strictly localized lavages. He presented a new drain which leaves the abdomen still a closed cavity. It is of glass with a projecting lip and two glass appendices, which keep it in place in the peritoneal cavity and ensure its permeability at all times. The outer end is fitted into a sterile condom in which the drained fluid accumulates, without allowing any contact with the outside air. Doyen also described a method of enterorrhaphy which can be applied to any part of the alimentary canal and has produced results surpassing expectations in some very serious cases requiring resection of a meter and more of the ileum and cecum with a neoplasm of 80 centimeters. He applies clamps above and below the portion to be ablated, which crush the middle and inner coats of the intestines, leaving only a thin wall which he ligates with silk. Two centimeters inside these ligatures he closes the intestine completely with clamps. He then cuts the intestine between the ligatures and the clamps, burning off with the thermocautery and pieces of the intestines still projecting and ligating the vessels of the mesentery as needed. The field of operation is thus cleared, absolutely aseptic. He then fastens the ends of the intestine firmly with a strong double thread, pushing the first silk thread inside after cutting it off close to the knot and performs lateral entero-anastomosis, either by closing the lower end alone and implanting the upper end over it or by uniting the two ends directly with a circular suture. When the end to end suture is made he detaches the mesentery a short distance and fastens the two superposed ends with two rows of stitches on the side toward the mesentery. He then sutures the outer free side, drawing the ligatures which close the intestine outside and cutting them. Elastic forceps applied above and below prevent the escape of the contents of the intestine. The suture is finished in a few seconds and the forceps removed, when the operation is concluded as usual. The complete anastomosis, the uninterrupted course of the canal, the double row of sutures and the absolute asepsis are the advantages of this method.

J. L. FAURE reported two cases of serious syncope, one fatal, from the chloroform in performing the operation of resection of the sympathetic in exophthalmic goiter (three cases), and he suggests that possibly resection may render the heart more susceptible to the effect of the chloroform. Doyen claims that his rapid method of thyroidectomy has obtained four absolute cures in four cases and that it abolishes the tachycardia, which is not affected by resection of the sympathetic. His first case has been permanently cured since 1887; his second since 1893. Kocher's statistics show the benignity of the operation, which only requires eight to fifteen, rarely twenty minutes, while the operation on the sympathetic is much more tedious. Faure also asserted that invagination of the stomach in gastro-enterostomy prevents the accumulation of food in the superior end of the intestine, which frequently entails serious results. He avoids this by inserting a piece of the stomach in the intestine in such a way that a buttonhole in the invaginated gastric cone, facing the lower end of the intestine, allows the passage of the food directly into it. The edge of the buttonhole is overcast to keep it open and the cone is securely sutured to the buttonhole in the intestine. Ligatures to produce atrophy in inoperable tumors have been revived lately in the new light of asepsis, and the results obtained amply justify further attempts. Tumors with a single pedicle are best adapted to this treatment, also uterine neoplasms. Tuffier ligated an advanced epithelioma of the latter class seventeen months ago and the improvement was decided and permanent to date. It is now completely mummified; he even doubted his diagnosis until confirmed by the microscope. He also secured marked improvement in an infection of one kidney by ligating the vascular pedicle. Broca has been comparatively successful with ligatures in neoplasms of the face, and Hartmann reported success in fibroma of the uterus which subsided to a remarkable extent, even when only one of the four pedicles is ligated. This treatment is also suggested for certain localized infections, megalosplenitis, phlebitis of the sinus, etc. The ligature can be applied to a vein or artery as indicated.

CHAPLUT stated that he had now a record of fourteen cases of plantar mal perforant, of which twelve were cured by elongation of the nerve after evacuation of the ulcer.

C. MARTIN of Lyons asserted, as the result of much experimentation with dogs, that it is possible to secure complete regeneration of a bone or articular extremity by supplying light and firm support as a guide for the ossification. He uses a framework of strips of platinum connected by cross-pieces, the size and shape of the missing bone. It holds the fragments apart, prevents the intrusion of the soft parts and can be filled inside with transplanted pieces of bone to assist the new formation.

DURET called attention to biliary lithiasis unaccompanied by icterus or tumor or the usual symptoms, and hence surgical intervention is frequently neglected, although it is the only means of relief from the intense pain, inflammation in the region of the gall bladder and progressive cachexia. It frequently dates from two to ten years previously. There are pronounced digestive disturbances, anorexia, finally neurasthenia and cachexia. The trouble is usually one or more stones lodged in the hypertrophied gall bladder, but without any accumulation of fluid. Cure was obtained in eleven out of his twelve cases.

General Report of the Berlin Leprosy Conference.

IS LEPROSY TRANSMITTED BY WEARING APPAREL?

Dr. VON BERGMANN of Riga said the answering of this question met with two hindrances: 1. The long incubation of leprosy in which it is difficult to decide whether in truth the incriminated object, say an article of clothing, has played the part of intermediary. 2. The gap which exists in relation to the vital conditions of the bacillus in our knowledge; for we have no positive notions as to its continued existence, its multiplication and the conditions under which its invasion takes place. According to Arning, Beavan Rake, Stallard, the bacillus can remain unchanged, even in decomposing water, for months, in relation to shape and colorability. The fact that any superficial slight injury of a leprosy makes possible the exit of crowds of bacilli into the external world is proved by the facility with which the smear cultures put in evidence the bacilli in the tuberculous form. Besides, the bacilli can easily be shown in the tumor secretion of the tuberculous form. We must say, therefore, that if the bacillus is recognized as the nosologic agent of leprosy, the bandages, the body and bed linen, even the clothes and shoes, are objects which have received an abundant bacillary material, and are therefore capable, given the proper condition, to infect another organism.

We meet in practice the statement that the transmission has taken place through objects such as clothes. These statements are, I repeat, difficult to control. In a case in which the patient maintained with peculiar emphasis that he had been infected by the clothes of his leprosy brother, which he wore after his death, it can be shown that in the lifetime of the brother there had been such relation between these two persons as to make a direct transmission very possible. The theoretically construed possibility of the spread of leprosy through infected objects can, however, obtain a practical background, if we consider the high percentage which the washerwomen furnish to the contingent of lepers, according to some reports as much as twenty per cent. of the patients. Of the present forty-nine female inmates of the Riga Leprosorium nine were laundresses. To be sure I can not prove that these women have really washed the linen of lepers. Positive statements have indeed been frequently made to me, but verification of the negative statements have not been practicable. Cotlin says that a family caught leprosy through infected water, as it turned out that dirty linen of lepers had been sunk into the well from which the water was taken. Cornil attributes, in one case, to the uncleaned official dwelling of a leprosy official the disease of his successor. He quotes at this occasion the old standpoint of the Mosaic law which declared the dwelling places of the lepers to be contaminated and gave prescriptions for their sanitation. However that may be, it is certain that until these still open questions are settled, we can not put aside the possibility of the transmission of leprosy through dirty linen, clothes, etc., and that we must take corresponding measures. It is, therefore, to be recommended that in the sanitary police regulations a careful disinfection of these objects, respectively, the burning of the same, be provided.

The sanitary police regulations must, moreover, include the disinfection of the dwellings of the lepers, as here, through uncleanness of all kinds, especially the spitting on the floor, bacilli deposits are formed which must be made harmless, the more so as the tenacity of the bacilli is very considerable and furnishes the essential condition of a long enduring virulence.

PRACTICAL NOTES.

Ordinary Bottles can be used for the Fluorids if they are first filled with melted paraffin, and then emptied while it is still warm and fluid. The thin layer of paraffin that adheres to the glass will protect it from the chemical.—*Bulletin de la Soc. de Pharm. de Bordeaux*, October.

Anein.—This substance, which has been described as an aqueous solution of acetone chloroform, has been brought forward by Vamossy as a substitute for cocaine; he says it is a good local anesthetic, free from toxic properties.—*Deutsche Medicinische Wochenschrift*.

Diagnosis of Intestinal Worms.—According to Muller de la Fuente, there are two signs which indicate the presence of worms; one is the sudden colic, the pain strictly localized, and the other is a marked contraction of the visual field on both sides.—*Gaz. Méd. de Liège*, November 11.

Hysteria as a Mark for Perityphilitis.—Rendue (*Gazette des Hôpitaux*) alludes to two cases in which the signs of perityphilitis were so counterfeited that an operation was deemed essential for the diagnosis. In one the mimicry persisted after the abdominal section, in the other it did not. He declares against an operation where there is no fever irrespective of other signs. This may be a point well taken.

Bisulphate of Sodium as a Lead Eliminator.—Peyron (*Centralbl. für innere Medizin*, 1897, 42) claims that a daily dose of 5 or 6 grains of the sodii bisulphite in lead poisoning with traces only in the urine, will eliminate as much as 72 mg. in a day. This remedy acts very rapidly, as the maximum excretion of lead occurred two or three hours after its ingestion.

For Inhalation in Catarrh of the Upper Air Passages.—Kafemann recommends as extremely effective the following combination: Menthol, 4; eucalyptol, 2.5; turpinol, 2; essence of pine, 1. A few drops of this liquid are poured into a bottle, which is warmed over an alcohol flame. Balsamic vapors immediately fill the bottle and these the patient inhales through a tube.—*Semaine Méd.*, November 17.

Treatment of Sciatica with Hydrochloric Acid.—The painful spot is painted with acid, hydrochlor. pur. with a camel's-hair brush, two to four coats. It smart a little, but the pain is relieved at once and radical cure follows in one to three weeks. Small blisters are apt to form and in painting the surface the second time, twenty-four to forty-eight hours later, the blistered spots must be avoided. (C. Gennatas, twelve cases; *Therap. Woch.*, November 7.)

Aid to the Early Diagnosis of Tuberculosis by Injections of Artificial Serum.—Twenty c.c. injected subcutaneously in a normal healthy person produce no febrile reaction, but in a person with tuberculous lesions the temperature rises to 38 or 39.5 degrees C., in the course of nine hours, returning to normal by the end of the twenty-four. The temperature must be taken commencing a few days before to determine the absence of fever, and every three hours afterward. The reaction is not positive unless the temperature attains 38 degrees.—*Semaine Méd.*, November 10.

Euquinin.—A new substitute for quinin has been introduced under the name of "euquinin" (*i. e.* superior quinin). Chemically described, it is quinin in which a hydrogen atom has been substituted by a molecule of ethyl carbonate. The product resembles quinin sulphate in appearance, but is almost wholly free from bitter taste; it gives the regular reactions for quinin. Therapeutically, it is said to not only possess all the virtues of quinin, but its range of application is much wider, and it has the advantage of inducing no secondary effects. Clinical reports so far speak of its successful application in fevers, neuralgia, whooping cough, and as a tonic in anemia and chlorosis.—*American Therapist*.

No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JANUARY 1, 1898.

TO COMPEL MIDWIVES TO REPORT CASES OF
PURULENT OPHTHALMIA OF INFANCY.

At the Meeting of the Association in Milwaukee, in 1893, resolutions were adopted by the Section on Ophthalmology approving of legislation which would compel midwives to promptly report cases of purulent ophthalmia of infancy to some legally qualified practitioner. As a result of the movement then inaugurated, midwives are obliged to report these cases in New York, Maine, Rhode Island, Connecticut, Minnesota, Ohio, Maryland, Missouri, Pennsylvania, Iowa, New Jersey, Illinois and Michigan, covering a population of over thirty-four millions. The prosecutions have not been numerous and still more rarely have midwives been severely punished for neglect in this respect. But the very existence of this law has had an admirable effect, and wherever a midwife has thus been brought to a sense of her duty, even by arrest, that has had a better effect upon the remainder of her class than all the lectures given and pamphlets published.

We call attention to this law for the reason that it should be passed also by the legislatures of other States and we trust that ophthalmologists, who most frequently see these sad results of ignorance and delay of midwives, will take the matter in hand, and also that medical journals in States without this provision will agitate the subject, so that when their legislatures convene, as most of them do about this time of the year, some move may be made to extend still further the effects of this beneficent law.

THE PATHOLOGIC MECHANISM OF TREMOR.

Although it is one of the most common of morbid motor symptoms and a very general accompaniment of states of weakness the phenomenon of tremor has not yet received a perfectly adequate or satisfactory explanation. We can conjecture of course its mechanism and assume, with DANA, that it is a derangement in the rhythm and force of the tonic influences proceeding from the brain to the muscles, or that it is in some way connected with impaired nervous conduction, but the underlying states that give rise to these lesions of function have not been made clear, nor has this been generally seriously attempted in the works treating of nervous disorders. We can say therefore with LANDON CARTER GRAY, in DERCUM's text-book of nervous diseases, that the intimate pathology of tremor has been so far an unknown quantity, notwithstanding all the clinical studies and pathologic investigations of the various disorders of which it is a characteristic symptom.

While it is true that as yet we have had no perfectly satisfactory theory of tremor, as regards, at least, its ultimate cause, one thing can be assumed as tolerably certain, that it is of central, and probably cerebral, rather than of peripheral origin. Some authorities have admitted the possibility of lesions of the peripheral motor tracts participating in its production, but this must be from interference with cerebral impulses rather than from the local lesions themselves and were conduction altogether interrupted it is not probable that tremor would occur. In a recent paper in the *Wiener medicinische Wochenschrift*, ADAMKIEWICZ reports the results of a clinical and experimental study of this subject, which seem to throw a certain possible light upon the possible pathologic mechanism of the symptom. He starts with the assumption that the phenomenon is of cerebral origin; there is no tremor that continues during sleep and from this it may be inferred that it is a phenomenon of active central innervation, over which however the will appears to have practically no control. It may be defined as a series of involuntary muscular movements of very brief duration, of central origin, and independent of the will. To demonstrate its character ADAMKIEWICZ employed the following experiment: A piece of laminaria was introduced under the dura mater of a rabbit, and its gradual expansion in that situation caused first spasm followed later by paralysis and spontaneous tremor. Tremor, therefore, he concludes is only a higher grade of spasm, and both, in spite of the pathologic increase of muscular tonus in spasm, are alike paralytic phenomena.

According to the view ADAMKIEWICZ adopts, normal muscular movement is the resultant of two opposed innervations, the one cerebral, passing from the cortex by way of the pyramidal tracts to the anterior horns, the other cerebellar, reaching the cornua through the

posterior columns. The one is the route of volitional impulses, the other that of tonic innervation. If the equilibrium of these is disturbed, by compression or otherwise, we have according to the part involved two varieties of motor disorders; if the pyramidal tracts, we have spasm or tremor from the uncontrolled cerebellar innervation; if the posterior columns, we have the disordered movements of ataxia. To explain how the tonicizing cerebellar fibers are put into action to produce tremor ADAMKIEWICZ assumes that, under pathologic conditions, they are excited by bodily movements, temperature, etc., and even by the normal heart pulse and the circulation, excitants that like other similar agencies are normally unfelt and only become irritants in conditions of disease.

Tremor can therefore be defined according to the ADAMKIEWICZ theory as the result of defective functioning of the pyramidal motor routes and a pathologic irritability of the tonic cerebellar fibers. It is a symptom of cortical motor weakness and may be caused, as he claims his pupils have shown, by any and all influences that diminish the energies of the cortical motor zones. This would explain, for example, how emotional disturbances may produce it, as their action is often directly weakening and can not be otherwise than cerebral in their action. In fact, any form of recognized tremor will readily come under this definition, except possibly that ascribed to peripheral lesions, and, if such ever occurs, the cause may also be ascribed to hindrance of cerebral innervation. All tremors are essentially identical in that they cease during sleep and are associated with muscular weakness, which when its source is sought is presumably of central origin. The theory that the function of the cerebellum includes the regulation of muscular tonus, though it has been questioned by some authorities, is apparently the one that is coming to be generally accepted and is strongly maintained by ANDRÉ THOMAS in one of the latest published memoirs on the anatomy and physiology of this organ. That, with impaired or lacking cerebral inhibition, this function may be pathologically hyperexcited so as to produce tremor is not only conceivable but highly probable according to all analogies and experience in pathology. Whether it is fully accepted or not, this theory of tremor offered by ADAMKIEWICZ appears to be on the whole as satisfactory a one as any yet proposed, both in its explanation of the presumed details of the mechanism of the symptom and in its agreement with admitted physiologic facts.

CONCERNING ATYPICAL TYPHOID FEVER AND PURE TYPHOIDAL SEPTICEMIA.

Atypical manifestations of typhoid fever are well known, not only to the clinicians but also to the pathologic anatomists. At the International Medical Congress, in Moscow, Professor CHIARI, of Prague,

reported the results of his studies concerning the atypical manifestations of typhoid.¹

Deviations from the usual or typical changes in this disease may occur in the following manner: 1. The typhoidal changes usually observed in the intestine, in the mesenteric glands, and in the spleen, may be peculiar. 2. Unusual inflammatory changes, due to the anomalous localization of the typhoid bacilli may be met with. 3. It may concern a general blood infection, without any definite localization, that is to say there may be a pure typhoidal septicemia.

In the intestine the typhoidal inflammation may be, so to speak, abnormal as regards its extent, its intensity and its localization. Thus the intestinal changes may involve not only the lower ileum but the whole small intestine and even the stomach, as well as the large intestine clear down to the anus. On the other hand, only a very few, and even but one single PEYER'S patch, may be involved. In some cases there may be very extensive inflammation and necrosis, involving all parts of the intestinal wall; in other cases the process remains confined to the mucosa, no necrosis occurs and it requires special attention in order to find the intestinal lesions. This last is, particularly, frequently observed in children. It may furthermore happen that there are no changes in the usual place in the lower ileum, but that the changes are confined wholly to the large intestine, or wholly to the stomach.

The mesenteric glands may be but slightly enlarged, or there may form very large swellings in which necrosis may occur to an even greater extent than in the intestinal foci.

The spleen varies greatly also as regards its changes. It may be but little enlarged, or the enlargement may reach a considerable extent. It may be accompanied with copious hemorrhages, foci of necrosis may arise, the capsule may be so stretched that in removing the organ it is ruptured, or it may rupture spontaneously during life.

Then, there are cases in which there is complete absence of all involvement of the gastro-intestinal tract, the only changes being in the mesenteric lymph nodes and the spleen; furthermore, cases occur in which a very marked acute splenic swelling perhaps leads to the postmortem diagnosis of typhoid fever, the so-called spleno-typhoids, of which a case has been described by KARLINSKI.²

As regards unusual localizations of typhoid bacilli and the resulting changes, then it may be said that there is perhaps no organ in which inflammatory processes, due to the bacillus typhosus, has not been observed. These were either complications in the course of otherwise anatomically typical fevers, or there were atypical typhoidal changes in the organs usually affected. Thus there have been observed purulent

¹ Zeitschrift f. Heilkunde, xviii, 1897.

² Wiener Med. Wochenschrift, 1891.

inflammations due to the typhoid bacillus, of the pleura, lung, thyroid gland, peritoneum, parotid gland, biliary passages, kidneys, testicles, the periosteum, bone marrow, joints, skin, subcutaneous tissue, muscles, meninges,³ endocardium and of the middle ear. Thus GUARNIERI⁴ describes a cholangitis due to the typhoid bacillus while the intestine was free from changes, the typhoid bacillus having been cultivated from the blood of the patient during life. KARLINSKI⁵ found in a case of acute splenic tumor, without changes in the mesenteric glands or intestine, two myocardial abscesses containing typhoid bacilli. The bacilli were also cultivated from the spleen, liver and kidneys.

The most interesting deviation from the normal of typhoid fever is the one in which there are no distinct local foci whatsoever, the postmortem examination showing only moderate splenic tumor, and yet the bacteriologic examination reveals the existence of general typhoid infection. Such cases must be regarded as pure typhoidal septicemias.

It is known that in other cases of typhoid there has occurred, in addition to the typical and atypical local changes, a greater or less distribution of bacilli throughout the whole body. In connection with this it will suffice to refer to the case reported by FLEXNER⁶ of typhoid septicemia, associated with abscesses in the kidneys. It is well known that the typhoid bacillus may be eliminated through the kidneys during the occurrence of the fever, and that it can be cultivated from the urine; it is also constantly found in the bone marrow during and after attacks of typhoid fever, showing that at some time during the disease a septicemia or invasion of the blood by the bacilli had taken place.

A pure typhoid septicemia has heretofore been described, most frequently in fetuses that were born by mothers sick with typhoid fever. The cases of so-called typhoid septicemia hitherto described have otherwise, in reality, been cases of atypical localization of the anatomic changes, with septicemia. In this connection it is well to bear in mind that there are those who claim that typhoid fever is under all circumstances a primary blood infection, and that the intestinal and other changes are secondary manifestations.

CHIARI then describes the cases of typhoid fever which were examined in his institute during the first five months of this year. The total number was nineteen cases, but in seven of these typhoid fever in the anatomic sense was not present; in six of these the positive result with WIDAL's serum test had led to the clinical diagnosis of typhoid fever, and in five of the seven it was found on bacteriologic examination that it really concerned a pure typhoidal septicemia with-

out any localized lesions. These cases, which are extensively described from a clinical, anatomic and bacteriologic standpoint, suggest the necessity for bearing in mind that when typhoid fever is endemic there may occur a pure typhoid septicemia, which may become confounded with other diseases, and furthermore, that when during life the serum test has given positive results we must be very careful not to exclude typhoid fever, even if the postmortem examination fails to show any of the local lesions characteristic of this disease, but to resort to a complete bacteriologic examination with reference to the presence of typhoid bacilli before reaching any definite opinion as to the nature of such a case. It may be seen that perhaps some of the observations that have appeared to point against the reliability of the serum test may not always rest upon sufficiently well taken grounds, and especially so when bacteriologic examination of the cases in question has not been made. It is well in this connection to remember that, as has also been studied by CHIARI, the gall bladder may act as a depot for typhoid bacilli, so that when a typhoid infection of the body has occurred bacilli are nearly always to be found in the gall bladder, even when other organs are sterile.

THE PROGNOSTIC IMPORTANCE OF THE APPEARANCE OF EYE LESIONS IN INTERSTITIAL NEPHRITIS.

There are few practitioners throughout the length and breadth of the land who do not, in the course of a year, meet with more or less classic instances of interstitial nephritis, commonly styled Bright's disease.

Although this renal lesion is encountered among rural dwellers, it is far more likely to proclaim its presence among those who by their devotion to urban life outrage Nature, and sooner or later pay the bill in chronic constipation, catarrhs, auto-intoxication in its myriad forms, in short all those disordered conditions that predispose to the final production of what SCHMEICHLER has aptly characterized as "connective tissue individuals," persons whose viscera and other highly specialized organs become the seat of interstitial processes. Thus is the foundation for interstitial nephritis laid, and though in its earliest phases the disease may be many sided, presenting a variation in subjective and objective symptoms often baffling to the practitioner, when the malady begins to unfold its classic features there is little likelihood of error in diagnosis. From this stage on to the last sad picture, the march of the process is more or less rapid according to the faithfulness with which the patient adheres to the dictum of his medical adviser. The disease may drag its weary length along, exhausting the utmost long-suffering and patience; or, on the other hand, in the midst of life the patient may be in death.

If such be the uncertainty as to the termination of

³ See article by Ohlmacher on typhoid meningitis in the *Journal* Aug. 28, 1897.

⁴ Quoted by Chiari, *loc. cit.*

⁵ *Journal of Path. and Bact.*, iii, 1895.

this process which, for convenience is called interstitial nephritis, it is the duty of the medical man to familiarize himself with those danger signals that are hung out from time to time in nearly all slow but fatal diseases. In the malady under discussion nothing is of more grave import than the appearance of lesions in the eye. This is not new truth, and yet it is truth that deserves far more recognition than has ever been accorded it. The advent of retinitis in the eye of an albuminuric heralds the beginning of degenerative changes in the area of distribution of the carotid arteries, seeing which it necessarily follows that similar degenerations and hemorrhages within the cranial cavity are to be anticipated. This sequel to interstitial nephritis is not uncommon and many ophthalmic workers have had their study of such cases cut short by cerebral hemorrhage. Indeed such a termination is not infrequent among those who are the subjects of hemorrhagic glaucoma, another terminal degenerative sign of interstitial kidney.

A study of the statistics of this subject is not without interest. Two years ago, BELT was led by his search through the literature of the subject into feeling that a more hopeful prognosis might be given in cases of Bright's if strict adherence to the family physician's counsel as to therapy, regimen and prophylaxis were observed. With this preconceived idea in view, BELT brought together the data of 409 cases furnished by most of the prominent ophthalmologists of the United States. But his hopes fell, for when the accumulated facts had been statistically arranged it was learned that of 409 individuals the subject of albuminuric retinitis due largely to living at the pace that kills, 155 were cases in private practice, of which number 62 per cent. died within one year, 85 per cent. in two years, and 15 per cent. lived more than two years. Of the 77 hospital cases, 85 per cent. died within one year, 93 per cent. within two years, and 7 per cent. lived more than two years. Of the remaining 187 mixed cases, 65 per cent. died within one year, 93 per cent. within two years, and 7 per cent. lived more than two years. And if these facts be properly collated, it is plainly shown that the large majority of the victims of albuminuric retinitis die within the first year after the appearance of the eye lesion, fully 90 per cent. die before the expiration of the second year from that time, while a scant 10 per cent. drag out a weary existence stretching over 10 years sometimes, and even to 17 years as in the minister reported by WEBSTER.

The value of accurate prognosis can not be overestimated. If it so happen that a physician's prognostications frequently fail of fulfillment he comes to be lightly viewed in the community and is held by his townspeople and brethren in the guild as a false prophet. On the other hand, the medical man should not be slow to prophecy when known facts are at

hand; for let his prognosis, even though they be filled with foreboding and gloom, come unflinching and timely to pass, and he will be laden with the confidence and increase of his patients, and they will forgive his shortcomings to seventy times seven. Such is the power of prophecy.

The foregoing statistics, then, establish a scientific truth of twofold value. First, in that it enables the practitioner to prognose intelligently in a given case; second, by reason of such authoritative prognosis, the sufferer, who is usually of the well-to-do class, may be acquainted with the suddenness with which his malady may terminate, permitting him to so arrange his worldly affairs as to set aside all necessity for the litigation that follows upon the death of most of those who are unfortunate or improvident enough to die intestate.

THE SOCIAL POSITION OF THE BRITISH MEDICAL PROFESSION.

The *Practitioner* has lately congratulated the British medical profession on the limited extent to which it suffered contamination from American medical science at the late (Montreal) meeting of the British Medical Association. The meeting in question was an excellent exhibit of how far philistinism has sunk British medicine beneath the level of American and continental (European) medical science. The section work in the main would not disgrace a third-rate American medical society of the mutual admiration type. The section on psychology, for example, sank far below the corresponding Section on Neurology and Medical Jurisprudence of the AMERICAN MEDICAL ASSOCIATION. In the last a European continental physician would find himself at home; in the first he would feel that, like Faust in Auerbach's *Keller*, he was among people,

With little wit and ease to suit them,
They whirl in narrow circling trails
Like kittens playing with their tails.

The downward social trend of the British medical profession, partly resultant on this philistinism and partly on its flunkeyism, appears evident, as the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION has already pointed out, in the award of honors in reward of medical eminence. While the SALISBURY administration has honored itself by the elevation of Sir JOSEPH LISTER to the peerage, the British medical profession has been hitherto condemned, as already pointed out in these columns, to the contemptible baronetage. The abolition of this is just now being demanded because of its notorious creation in the STUARTS' day by what MACAULAY ("Political Georgics," 1828) calls

Boodles' patriot band
Fat from the leanness of the plundered land.

It must in justice be admitted that there is a decided flunkeyism in the British medical profession which about two decades ago found expression in an animated discussion over the method of shaking hands with different ranks, whether the practitioner should not always ring the servants' doorbell and the like very caddish topics. Letters on these matters overflowed the columns of the *Lancet*, *British Medical Journal*, *Medical Times and Gazette* and the *Medical Press and Circular*. The whole subject was finally summed up by a "veteran practitioner of fifty-one years' standing" in the *Medical Times and Gazette*. "My practice," he remarks, "has been to ring the visitors' bell gently, though even that, when calling to see a servant, has seemed to me to savor of impropriety. But whatever course the young doctor adopts, let him above all things beware of using the knocker. That would imply familiarity with the family, the very suspicion of which it behooves the circumspect practitioner to avoid. So long as he confines his manipulations to the bell-pull, he is safe. The next problem which confronts him is what to do with his hat. Following the custom of other men who have business in the house, he should by rights leave it in the hall, not on the floor but on the hall table. This course however may involve him in serious danger. If there are children about the house they may be counted upon to play with it, perhaps march into the drawing-room with it on their heads, a complication, I need hardly say, as being evidence of undue familiarity would be of the gravest import. My own plan has been to take my hat with me and only relinquish it when the clinical investigations of a case rendered such a course absolutely necessary. Familiarity is impossible so long as the hand keeps touch of the beaver. It is an almost impregnable rampart and would take the sting out of anything a tale-bearing domestic may say hereafter. The ethics and equity of handshaking form a difficult subject. As a rule, I agree with the *Lancet* that it is best to avoid it. If a lady of title offer two jeweled fingers the young practitioner would be at once foolish and rude to decline to take them, but the touch should be cold and momentary. With the wives of commoners it will be best if it can be done without obvious rudeness, to bow formally instead of offering to shake hands, both on entering and leaving."

THACKERAY voiced the feeling of the British county snobocracy toward the medical profession in Dr. Pen-dennis. He, after achieving a competency, became a member of the squire-archy and felt it as deep a disgrace to be styled "Doctor" as he had previously felt it to be an honor. American judges, notorious as many of them are for defiance of science, would hardly go to the extent of the English judge of county snobocracy ancestry who decided that a bill against a county magnate for treatment of scarlatina in a child,

was an extortion since no child could have scarlatina without being confined to bed. In this the judge but imitated the conduct of Queen VICTORIA in the Lady FLORA HASTINGS case. This young lady, when a maid of honor, began to exhibit signs of abdominal enlargement. The gossips of the court loudly hinted that she was pregnant and their view was adopted by the Queen. The majority of the court physicians declared, after a vaginal examination, that the unfortunate girl was not pregnant but suffered from a malignant tumor. Queen VICTORIA ignored their opinion, drove Lady FLORA HASTINGS from the court in disgrace, deprived the most manly of the court physicians of their places and ostracized those by whom they were employed. The rapid development of the abdominal enlargement soon threw pregnancy out of the question. On the girl's death a necropsy revealed the existence of uterine sarcoma. No public amends were made to the memory of the unfortunate girl. The court authorities deprived the girl's father of a court office. The medical men who made the necropsy were subjected to scurrility and persecution by the court clique, which was finally ended by suit for libel. Had the mass of the British medical profession been anything but flunkeys of the time of the type of the "veteran of fifty-one years' practice," no head of a constitutional government would have dared to insult them for a conscientious clearly impartial necropsy. The contamination the *Practitioner* fears from the American medical profession, is the infusion of self-respect which might destroy the flunkeyism exhibited in the controversy over doorbell ringing and handshaking just quoted.

CORRESPONDENCE.

Department of Public Health.

WASHINGTON, Dec. 7, 1897.

Honorable FRANK S. GARDNER, Secretary New York Board of Trade and Transportation, New York City.

Dear Sir:—Having seen a letter addressed to yourself by Warren E. Anderson, dated Pensacola, Florida, Nov. 24, 1897, and published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* in which this gentleman undertakes a serial criticism of "The Efficiency of the Marine-Hospital Service in the conduct of Federal Health Affairs," and which he states is made "without malice toward any one or animus of a personal character whatever," I take the liberty of stating to you that there appeared before a board of examiners of the Marine-Hospital Service in June, 1883, one Warren E. Anderson, a native of Marianna, Florida, and a graduate of the Medical College of Alabama. It may be interesting for you to inquire whether the gentleman who writes to you upon the character and abilities of the officers of the Marine-Hospital Service is this same Warren E. Anderson, who stood lowest in a class of eleven candidates for appointment in the Service, and was rejected on account of lack of professional attainments. If this shall prove to be the same gentleman it will serve to explain the animus contained in his letter.

Referring to his first objection as to the age of officers enter-

ing the Service, he has misstated the maximum age of applicants who are eligible for appointment, which is 30 years instead of 28 as stated by him. Particular information upon this specious objection as to the age qualifications of the officers of this Service is to be found on pages 11 and 12 of an "Address" by the Supervising Surgeon-General of the Marine-Hospital Service, in which it will be seen that the average age of the sixteen surgeons is 50 years, the average age of the twenty-six passed assistant surgeons is 35, and of the nineteen assistant surgeons, 29 years.

Referring to his second objection that less than 5 per cent. of the officers of the Service belong south of latitude 37. This misstatement may be dismissed at once by pronouncing it an untruth. The official list of the officers of the Service is inclosed, from which you will see that over 50 per cent. of the officers of the Service were born south of Mason and Dixon's line.

Instead of 10 per cent. of the regular officers of the Service who have had experience with yellow fever, at least 25 per cent. have been connected with one epidemic or another during the last twenty years.

Of other portions of his letter, which are mere expressions of his opinion as to the efficiency of the work of this Service, I shall not attempt a refutation, as you will have already concluded by the statements above given, taken from the records of this Bureau, that he is ignorant of the personnel of this Service, and if it shall prove that he is the person who was rejected as unfit for appointment on account of lack of professional qualifications, his "animus of a personal character" must vitiate all other views which he professes to hold concerning the Service.

I shall mail to you under separate cover an official list of the officers of the Service, with marks to indicate those who have served in epidemics of yellow fever in the past twenty years, an "Address" on the Public Health Service in the United States, together with the "Address" of the Supervising Surgeon-General before the Committee on Interstate and Foreign Commerce of the House of Representatives in 1894, all of which will give you official and accurate information upon the points which have been misstated to you by your correspondent.

Very truly yours,

[Signed] CHARLES E. BANKS, Surgeon M.-H. S.

PENSACOLA, FLA., Dec. 15, 1897.

HON. FRANK S. GARDNER,

Secretary Board of Trade and Transportation, New York City.

Dear Sir:—Please accept many thanks for your valued favor of the 8th instant, with enclosure, dated Washington, Dec. 7, 1897.

I had hoped that the calm, dispassionate reason of man would prevail in the discussion so auspiciously begun by us during the past summer, and which gave promise of rich reward so far as the advancement of the health interests of our country was concerned. The sudden and violent interjection, however, into this hitherto friendly contest, of the unwarranted, wanton, unjust and unmanly personal attack upon me by an *attaché* of the United States Marine-Hospital Bureau at Washington, in a recent letter to you, would seem to have disturbed, temporarily, at least, that serenity and peace of mind so necessary to the performance of a task undertaken in behalf of the public weal. I must confess that I was both surprised and pained upon reading the communication of Surgeon Banks to you, and sincerely regret that the incident should demand any notice, whatever, at my hands. I was surprised because I was ignorant of the fact that it had become a settled policy of the departments of our government, to suppress debate of important public questions, by a resort to personal attack upon the quiet, unoffending (but tax-paying citizen) of the Republic. I was pained that an imputation so base, so cowardly, so reck-

less and so false should be made against the honesty of my motives. For the past fifteen years I have lived in this community, and in that time have won the respect and esteem of the people. I have held important public offices by both appointment of the governors of the State and election of the people, but no one has ever before questioned my integrity, or doubted the sincerity of my purpose. That it should be done now by one I never saw or knew, one whom I have never even criticized, is indeed inexplicable. Objectionable *systems* I always condemn and attack; *men*, simply as such, never.

If you will bear with me for a few moments, I will relate as briefly as possible the following facts: In 1883 I was examined in Washington by a Board of Examining Surgeons of the Marine-Hospital Service, in company with *nineteen or twenty* other applicants for a vacancy then existing. The examination began Monday forenoon of May 28, and by *Thursday* the class has been reduced to *eleven*, the others having failed to keep up the required daily average of 70. Saturday night, after having stood the examination to the close, I met the Surgeon-General, Dr. John B. Hamilton, who, in answer to a question, stated that I had "failed to get this appointment;" that several—three or four—were ahead of me; that, "results of these examinations being *secret*, I can not tell you just how you have been rated by the Board." He further urged me to appear again the following year, provided a vacancy occurred. Returning home, the Surgeon-General sent me an *appointment* to the Station at Indianola, Texas, as Acting-Assistant Surgeon. Yet, Surgeon Banks says I "*was rejected for appointment on account of lack of professional qualifications.*" Surely, with access to the *secret* archives of the Bureau, he should not have withheld half of the truth to suit his own purpose! I reported at Indianola, but not liking the location, resigned and returned to Pensacola, where I have resided since, and, so far, without occasion to regret the "alleged failure" before the Board of Examining Surgeons; and the episode itself has long since been lost to memory in the activity of a busy, professional life.

It would seem to me, however, that the people care nothing as to how Warren E. Anderson was rated on examination in 1883; how Charles E. Banks stood in his class; whether he was examined at all, or whether he secured his present lofty position by political "pull," or personal favoritism. They do desire to have, though, a free, fair and unbiased discussion of the subjects of quarantine, and the prevention of epidemic disease. The enemies of the Little Corsican pointed with derision to his repeated failures on examination, but military critics point with impartial pride to Rivoli, to Arcola, to Austerlitz, to Marengo, to Jena, to Friedland, to the conquest of a Continent, as his title to undying fame! Millions of people have long since forgotten that the hero of the civil war stood amongst the lowest of his class at West Point, but they all remember that on an eventful day in April, 1865, he stood first in glory of arms on the field of Appomattox, and first of all men in that noblest of attributes—*magnanimity*! Your Washington correspondent might make the attempt to emulate this illustrious example, in this one particular.

Personally, however, I care naught for the reflections of Surgeon Banks upon my professional ability of fifteen years ago, or now. I know nothing (and care less) of his attainments, past or present; but his letter indicates clearly that the test of gentlemanly bearing was not applied to his case, or he would now be engaged in earning a livelihood at some honest trade on the sandy beach of the Atlantic Ocean, or the rocky sides of the snow capped hills of Maine.

In dismissing forever, I hope, the personal references of Surgeon Banks' letter (there was nothing else in it), I would say that a cause requiring the use of such infamous methods as those employed by him, is surely in a high state of decomposition; far beyond the reach of moral disinfectants. But how

horrible in contemplation even, the control of our health affairs by a man who could write the letter to you from Washington dated Dec. 7, 1897, and yet he stands, I believe, in line of promotion!

It might be well for you to determine the actuating motive of all those earnest advocates of a separate Department of Public Health; and whether or not Doty and Girdner and Wingate and Porter and Bloxham, the members of the AMERICAN MEDICAL and American Public Health Associations, the press of the South (almost without exception) have had their youthful aspirations clipped by boards of examining surgeons; and if so, shall they be frightened away by the skeletons of a long-forgotten past, exhumed in ghoulish glæ from secret archives of the Marine-Hospital Service by your correspondent? It must be so, according to the only argument he has advanced in his letter.

For your information, I will say, that for the past fifteen years I have had ample opportunity of studying yellow fever epidemics in the South. My knowledge of their management has been obtained by both personal observation and reports of the public press, and I believe this information to be as accurate as any furnished by the Marine-Hospital Service. That, in the main, the facts detailed in my letter to you, of the 24th ultimo, are correct, no truthful man acquainted with contemporaneous history can deny. The discrepancy of two years in the "age qualification" is immaterial to my argument, and was an unintentional error. The following clippings, taken from the *New Orleans Item* may prove the correctness of another point made by me:

"A number of Marine Hospital, local physicians, and Health Officer Porter of Florida, all yellow fever experts, had a reunion yesterday in the rotunda of the St. Charles Hotel, and the proposed National system of quarantine was liberally discussed. The Marine Hospital men admitted to having just seven officers in their service who had faced Yellow Jack. Seven physicians, however expert, are hardly adequate to protect the yellow fever frontiers, extending from Charleston, S. C., to the mouth of the Rio Grande, and they admitted this fact."

"It now develops, by the T. D. system of deferential, that the Marine Hospital corps have very few officers who have any experience or practical knowledge of yellow fever. They have just six officers out of sixty-five and *The Item* has repeatedly published this fact during the past three months."

Your Washington correspondent would have it appear that I thought too few of the officers of the service came from "south of Mason and Dixon's line," whereas I made no such reference to that historic landmark, but stated that only a small percentage of them came from "south of latitude 37, or that area of the country likely to be invaded by yellow fever," meaning more particularly the Gulf States.

In conclusion, allow me to say, that my "earnest protest" contained no personal reflection upon any officer of the Marine-Hospital Service, many of whom I know, respect and honor; that it was conceived with as little malice as one could find in the breast of a new-born babe.

To Surgeon Banks I would commend, observing his ignorant disregard of the golden law of Christ, the injunction of Allah's prophet: "Be moderate in your speech, for the most unwelcome of all voices is the voice of an ass."

I shall refuse further notice of this gentleman, and trust that he may not again disturb the peaceful trend of my thoughts.

The letter from Washington having been published in the *Evening Post*, I would request the same courtesy be shown me.

Very truly yours, WARREN E. ANDERSON, M.D.

Curettage of the Uterus in Incomplete Abortion.

FT. ADAMS, R. I., Dec. 21, 1897.

To the Editor:—In the JOURNAL of Nov. 27 and Dec. 11, 1897, articles appeared on the treatment of inevitable abortion, and I present the following history of a patient in which curet-

tage was performed as a means of emptying the uterus of the retained secundines, which resulted in the prompt recovery of the patient from an almost moribund condition.

The patient, a female of middle age, multipara, anemic and debilitated, while about her household duties suddenly fell to the floor from continuous loss of blood, which had been a prominent symptom for several days and had been attributed to a more than usually profuse catamenia. All knowledge of a probable pregnancy was denied.

Pain and hemorrhage were very pronounced symptoms, and the patient was at once placed in bed, the foot end raised, morphia and viburnum were administered *pro re nata*; the hemorrhage and pain were relieved for a few hours, only to reappear with renewed force. An examination showed the cervix to be soft and dilated. The lower uterine segment was compressible and softened. The general condition of the patient was very bad, lips white, cornea glassy, radial pulse not perceptible, extremities cold. Upon approaching the bed the patient vomited and sank back utterly exhausted. Subcutaneous injections of strychnin, saline solution and brandy brought about reaction, and chloroform was administered at once; anesthesia was prompt and a remarkably small amount of the chloroform sufficed. The patient was placed in a dorsal position on the Kelly's pad, the cervix drawn down and dilated with steel dilators. An irrigating sharp curette was introduced and the uterus was thoroughly cleaned out. Large pieces of placental tissue were removed but no signs of the fetus were observed. The hemorrhage promptly stopped and the uterus contracted well. A strip of iodoform gauze was introduced into the uterine cavity and allowed to remain twenty-four hours. The patient was removed to another bed and recovered without experiencing further pain, nor was there any subsequent rise of temperature. The bedding from which the patient was removed was saturated with blood to an astonishing degree.

It can probably safely be asserted that the safety of patients suffering from abortion lies in the prompt relief and abatement of the alarming symptoms, allowing the pregnancy to continue, or the evacuation of the uterus of all the products of conception. The immediate and remote dangers of abortion are many, any one of which might end fatally. If it is determined that a case of abortion is inevitable, the sooner the uterus is empty the safer for the patient. If surgical intervention will accomplish this object with less suffering, and avert such possible complications as hemorrhage, putrid intoxication, septicemia and peritonitis, suppurative arthritis, embolism, tetanus and chronic uterine disease, its general adoption would seem to be commendable.

WILLIAM ROBERTS, M.D.,
Hospital Steward, U. S. Army.

The New York Medical League and the Sick Poor.

NEW YORK CITY, Dec. 15, 1897.

To the Editor:—Many good people are suffering from the apprehension, and misapprehension, that the New York Medical League is opposing charity to the sick poor. This is entirely foreign to the purposes of that body, therefore we are directed to communicate to you and, by courtesy, through you to the public, the following statement:

The New York Medical League believes:

1. That there is not enough charity work done in this city.
2. That there is too much of the benevolence business transacted. That many worthy poor are deprived of the alms provided for them, because all those alms do not reach the truly needy through the proper direct channels. And that it is a shame that any institution should show handsome annual profits and yet beg for city money, especially when its earnings represent monies derived from the poor.
3. That all dispensaries, etc., should be free, for it is a cruel

and unnecessary hardship to ask poverty-stricken persons to pay anything for medicines or surgical appliances.

4. That it is a bad policy to give city money to private institutions, to the detriment and loss of the public ones appointed for the care of the sick poor. We believe that the city institutions should be repaired, improved in sanitation and illumination, and should furnish larger and better accommodations. The city money should be used to give better food, warmth and clothing to the patients under treatment in the city hospitals.

5. It is all wrong to give public money to medical colleges; the profits go into the pockets of the faculty or into the institution. These incorporated colleges are close corporations and just as much money-making enterprises as a grocery store and a gas company.

6. It is an outrage that the public institutions should be obliged to maintain a patient on less than thirty cents a day, while the city gives over one dollar per day to private institutions for the same work.

7. The Board of Estimate and Apportionment stood a tie, two to two, and the chairman cast the deciding vote. Therefore, the Mayor is responsible for the fact that the municipal institutions will be a reproach to our city because the money that should have gone for their urgent necessities has been given away. As he himself stated in a certain case, it was given because he knew the man interested.

8. The tax-payers are willing that private persons should give their own money, but we do not believe they approve of any diversion of public money away from the public institutions, or of any gift of the same to close corporations.

9. Finally, we wish to state that in the large gathering that protested, there were representatives of tax-payers' associations, business men, etc. The doctors were there simply to give evidence against the farce behind the scenes, partially veiled by the mantle of a so called charity.

DOUGLAS H. STEWART, M.D.,
Cor. Sec., New York Medical League.

License in Germany.

DETROIT, MICH., Dec. 20, 1897.

To the Editor:—Dr. B. Becker's friendly corrections and suggestions concerning the licensing of physicians in Germany are to the point, but in some instances incorrect. While the subject is too unimportant to consume much of your space, once begun, I believe in finishing anything correctly.

An American graduate in medicine, in order to matriculate at a German university needs possess no further documents than his diploma and passport. Whether or not an A.B. or A.M. degree of this country would be considered an equivalent by the German authorities of a *testimonium maturitatis* I am not prepared to say. Any physician desiring to leave this country for the sake of engaging in the practice of medicine in Germany where, by the way, there is absolutely no demand for a foreign physician, can get the necessary particulars by addressing either Seine Magnificenz p. t. Decanus der medicinischen Fakultät der Universität (Berlin, etc.), or the Board of Examiners.

The study in the preparatory school, gymnasium, embraces a curriculum of fourteen semesters (seven years) only. A young man may enter the university at the age of 17 years. Dr. Becker is correct concerning the statements that such universities as Johns Hopkins, Harvard, etc., are not considered equivalent to a German university. Any United States medical college in good standing with the Association of American Medical colleges is "OK" as far as this goes in Germany.

If the government calls a physician, surgeon or scientist to a chair in a university, even if he be a graduate from a so-called irregular college in this country, he is immediately licensed to

practice medicine without any further ceremonies. Occasionally a great foreign physician (and there are plenty of them here) will get special privileges from the Minister (secretary) of Education. So, for instance, I am satisfied that such men as Senn, Osler and others, whose works are considered standard all over the civilized world, would have but little difficulty in getting a state license, without the prescribed examination. Germany honors even foreigners, if they deserve it.

In addition I beg to say that in Germany exists a law called *Gewerbefreiheit*, giving everybody the privilege of practicing medicine, forbidding him to call himself doctor or signing himself *practischer Arzt*. He can also not sign death certificates and there are a good many more privileges he does not enjoy.

An American physician could have a sign reading: "Dr. N. N., approbiert in Amerika."

The statement made by Dr. Becker, that the requirements are practically the same all over Europe is erroneous, for in Austria, for instance, an American diploma gives the holder but little if any standing, even when he wants to matriculate as a student. He would have to begin like a freshman.

In conclusion I beg to say that it would be a very good idea for the editorial management of the JOURNAL to publish a *résumé* of the laws governing the practice of medicine in all countries. There are many South American, African and Asiatic countries where American physicians would find a great field of work, but they are ignorant as to whether or not they are authorized to engage in the practice of medicine there.

How difficult it might be for a poor physician, who seeks his health in the South, to pass an examination in Spanish or French and pay a large fee when he intends to practice among American or European settlers only, is plain.

I thank Dr. Becker for the trouble he has taken; and "A Reader," the original inquirer, might do well to first write to the Board of Examiners, in the city he intends to settle, before crossing the ocean. Very truly yours,

GUSTAVUS M. BLECH, M.D.

Practical Prophylaxis.

CHICAGO, Dec. 26, 1897.

To the Editor:—As medical men who believe in prophylaxis, we are in duty bound to do all in our power to prevent disease and suffering. Most diseases are caused by improper food, bad air, lack of sunlight, exposure, bad occupation, worry, overwork, heavy work, irregularity, unsuitable climate, traumatism, or alcohol. These causes are mostly the results of poverty. We all know only too well the effects of poverty's surroundings upon moral, mental and physical health. When ten years of poverty will cause adults to deteriorate and often become criminals or commit suicide, is it any wonder that children should be warped mentally, morally and physically for life?

Poverty is without doubt the chief cause of degeneration, child labor, drunkenness, crime, anxiety, disease, insanity, suicide, dead-beats, charitable institutions, dispensaries, etc. If we would prevent the greater part of this, we must prevent poverty.

Poverty and destitution always begin at the exact point where men can not get a chance to use land and machinery; because the former is the source of all food and shelter, and the latter is the only civilized means of obtaining food and shelter from the source. We can easily imagine what would happen if the source of water and the means of reaching it were all controlled by private interests. You can actually see and feel the effects of having the source and means of getting food and shelter controlled by private interests.

Food and shelter are as necessary as water, therefore the same common sense which has given us public control of enough of the water-supply and highways to accommodate

those who have not private water, should also demand that enough available land and machinery be reserved under public control to accommodate those who have not free access to that under private control. Then no one could be denied an opportunity to produce food and shelter or their equivalent. Poverty and destitution would be practically impossible and consequently disappear.

Now, "available land and machinery reserved under public control" is simply necessary business or industry owned, operated and monopolized by the Government. For instance, the U. S. mail service. In other words, the Government should own, operate and monopolize enough lines of necessary industry, at fair wages, so that by reducing the hours of labor it can provide work for the unemployed. We estimate that public control of the railroads, express, telegraph, coal mines, car lines, telephone, light and water systems, at the eight hour day, would about take up the unemployed. This would put about two million idle men to work, thus incidentally give us two million more patients, do away with dispensaries, charitable institutions and dead-beats, remove the pressure which is crowding the medical profession as well as all trades, and also be the grandest prophylactic measure ever instituted. What could be more fitting than for the medical profession to take the lead in this reform?

We are trying to distribute as widely as possible, circulars fully describing this reform, and therefore we earnestly ask all members of the medical profession to please send stamped and addressed envelope for some of the circulars. It will help a most worthy undertaking and greatly oblige,

Yours for practical prophylaxis,

MAURICE F. DOTY, M.D.

An Acknowledgement.

NEW YORK, Dec. 25, 1897.

To the Editor:—Will you allow me to correct an omission and acknowledge my indebtedness to my friend Dr. F. S. Mandelbaum, for the photographs illustrating my article on "Van Arsdale's Triangular Splint for Fracture of the Shaft of the Femur," etc., in your issue of Dec. 18, 1897.

Yours fraternally, A. ERNEST GALLANT, M.D.

Per Os, not "Orem."

NEW YORK CITY, Dec. 25, 1897.

To the Editor:—Thanks to "F" (page 1284, column 2, lines 46 to 51, JOURNAL, Dec. 18, 1897), because I had rather be right than wrong; because Daniel Webster said that he "would not give a cent for a man who never made a mistake"; because Ambassador Phelps said, "a man who never made a mistake never made anything," and because our beloved, great and honored Dr. Lewis A. Sayre said that he was "thankful for any true criticism, no matter how sharp, keen or cutting."

Respectfully yours, EPHRAIM CUTTER, Sr., M.D.

SOCIETY NEWS.

Resolutions Adopted at the Meeting of the Boston Medical Society, Dec. 18, 1897.—

WHEREAS, The unrestricted abuse of medical charity in the large hospitals and dispensaries of Boston is being seriously complained of by a large number of general practitioners; and

WHEREAS, The State has granted charters to these hospitals and dispensaries for the definite purpose of giving medical and surgical care and treatment to indigent persons within this city and Commonwealth; and

WHEREAS, The Boston Medical Society, individually and collectively, recognize, with every feeling of sympathy, the rights and just claims of some of our citizens to the benefits of public and private charity, and will not be found wanting in generosity in whatever may tend to foster the moral, social and physical well being of the sick, the poor, the destitute, the lowly, the worthy and the unfortunate; and

WHEREAS, Large numbers of persons of both sexes frequently, daily and repeatedly receive medical and surgical advice and treatment gratuitously for numerous cases of minor surgery and ordinary illness, who are believed to be financially competent to pay moderate fees; and

WHEREAS, The time, facilities and attention at the dispensaries being necessarily limited, that which is received by the well-to-do and the undeserving is, in that proportion, withheld from those who by chartered rules of those institutions are justly entitled to their benefits; and,

WHEREAS, The practitioners of medicine and surgery of any community who have duly graduated from accredited medical colleges and have incurred the expense of locating in such communities naturally and justly feel that their present and prospective rights and privileges are wrongly encroached upon by the abuses now in practice in connection with medical charities; therefore, be it

Resolved, That it is the opinion of this Society that some means can be found to check or modify this formidable evil; and

Resolved, That an urgent call be made upon all such members of the profession who are in sympathy with this movement and have at heart the best interests of the medical profession, to render such moral assistance and financial support in the adoption of such measures as will tend to eradicate and prevent these evils, abuses and practices; and

Resolved, That an open meeting be held at some future time and the profession at large be invited to be present; and

Resolved, That a copy of these resolutions be sent to the *Boston Medical and Surgical Journal*, the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, the *Medical Record*, the *New York Medical Journal* and the *Medical News* for publication.

M. GERSTEIN, M.D., Secretary.

BOOK NOTICES.

Manuali Hoepii Sieroterapia. DEL DOTTOR EMILIO REBUSCHINI. U. Hoepli, Milano, 1897. Pp. viii, 421. (Manual of Serotherapy. By Dr. Emilio Rebuschini.)

This is another of the little Hoepli manuals, which must be very convenient to Italian students and physicians. Its bulk of 421 pages of closely printed text shows that it is more than a brief compendium; it is in fact a very fair compilation of the principal facts of serotherapy up to within the past year or two, apparently fairly and judiciously stated. The work takes up each disorder that has been thus treated or experimented with, from the earlier attempt of Pasteur, Behring and others, down to Sanarelli's latest claims as to the serotherapy of yellow fever. The literature appears to have been very carefully gone over, and American data are not overlooked, as was formerly often the case in European compilations of this nature. To any one who can read Italian this would be a very handy ready reference work.

Fiftieth Anniversary of the Hartford Medical Society, September 15, 1846. Proceedings of the celebration October 26, 1896, at Hartford, Conn.

This volume includes the introductory remarks by the president, M. Storrs, M.D. Historic addresses by Gurdon W. Russell, M.D., on the deceased members and those connected with the later years of the Society, by Horace S. Fuller, M.D. "Esprit de Corps" by Henry P. Stearns; The present and future of the Hartford Medical Society as suggested by a study of the fundamental enactments, by Melancthon Storrs, M.D.

The smooth and pleasant course of the Hartford Medical Society from the foundation in 1846 to the present time made it a pleasant task for the members to meet and celebrate the occasion. No one can peruse the work without feeling that they missed a very important event by not being present. This commemorative volume is of interest to every member of the medical profession, and the biographies contained in Dr. Fuller's address add something to American medical biographies.

Some of the speeches on the occasion of the anniversary dinner were of a high order of literary merit, and all were amusing and entertaining.

The Hartford Medical Society, judging from this volume, is composed of very pleasant people.

Transactions of the Iowa State Medical Society, Vol. xv. Cloth. Illustrated. 400 pages. 1897.

This book contains the proceedings of the forty-sixth annual session of the Society, held at Marshalltown, Iowa, May 19, 20 and 21, 1897. Besides lists of members, auxiliary societies, obituary notices, etc., the forty papers presented at the annual meeting are given in full. The volume is well bound, well edited and on excellent paper, a credit to the society.

Proceedings of the Florida Medical Association. Paper. 85 pages. 1897.

The proceedings of the twenty-fourth annual meeting of the Association, held at Palatka, Fla., April 1897, are given in this volume. The appendix contains the various papers presented at the meeting, lists of members, etc.

NECROLOGY.

JOSEPH LEWIS, M.D., Vienna University, Austria, 1847, died at his home in Albany, N. Y., December 19. He was born in Radnitz, Bohemia, August 17, 1820 and came to Albany in 1849. Having obtained prominence by both industry and skill he served with Drs. Thomas Hun, Alden March and Mason F. Cogswell on the board for the examination of New York surgeons for the U. S. Volunteer forces. He was an ex-President of the Albany County Medical Society, the senior censor of the New York Medical Society and a consulting physician on the staff of the Albany Hospital. From the lay press we gather that notwithstanding his robust health which began to fail last spring, he died of some affection of the liver.

Prof. E. S. TARNIER, Paris, aged 69. One of the most notable medical figures of our epoch, an accomplished scientist, instructor and author. His greatest work was along the line of obstetrics, which has rendered his name familiar to every member of the medical world in both hemispheres. In 1882 he proclaimed the necessity of isolation for puerperal fever, and to him we also owe the wide-spread use of sublimate and numerous obstetric appliances. His basiotribe, cephalotribe, dilator, incubator and forceps have rendered incalculable service, and the latest models are still fashioned upon their principles. France recognizes the debt she owes to Tarnier and the clinic with which he has been so long connected, is to be called henceforth the *Clinique Tarnier*. He has been president of the Société de Chirurgie, of the Académie de Méd. and of the Soc. Obstet. de France. The list of his works is given in the *Progrès Méd.* of December 4, but his great "Treatise of the Art of Accouchement" is left unfinished, although two volumes have already appeared, and 700 pages of the third are in press. His pupils who have been assisting him intend to complete the work, making every effort to render it worthy of the master.

STEPHEN H. CONGER, M.D., College of Physicians and Surgeons, New York, 1843, of Summit, N. J., dropped dead in the Delaware, Lackawanna & Western Railroad waiting room on December 21. He came to Summit from New York in 1870, was aged 76 years and leaves a widow and two sons.

RAYMOND L. HELLER, M.D., Napokon, Ohio, December 14, aged 26 years.—P. E. Sandridge, M.D., Nelson, Mo., December 13, aged 66 years.—C. A. Thompson, M.D., Jefferson City, Mo., December 15, aged 71 years. During the war he was surgeon of the Thirteenth and Nineteenth Illinois regiments for four years. He was a prominent figure in the State Medical Association and was treasurer of that body for eighteen years.—Charles H. Jones, M.D., Baltimore, Md., December 17.—William Voorhees, M.D., Spottsylvania, Va., December 19, aged 62 years.—E. E. Bringer, M.D., Pittsburgh, Pa., December 19, aged 28 years.

J. B. LARGEAU, one of the younger surgeons of France, outside of Paris, whose name is well known by his communications to the Soc. de Chir. and the *Archives Progr. de Chir.*, of which he was one of the founders.—R. Branchet y Vinc Pradat, professor of hygiene at Granada, Spain.—Max

Burchardt, privat docent of ophthalmology at Berlin, Graefe's successor at the Charité.—L. Auerbach, professor ex. of histology at Breslau, aged 68 years.—Edmund Drechsel, professor of physiologic chemistry and pharmacology at Berne, aged 54 years, and noted for his investigations of the properties and products of the albuminoids, origin of urea, etc.—L. A. Buchner, aged 84 years, senior member of the medical faculty at Munich, formerly professor of pharmacology.

PUBLIC HEALTH.

Health in Chicago.—The report for November gives the total deaths as 1,613, or 0.99 per 1,000, the rate for the same period in 1896 being 0.97 per 1,000. These 1,613 deaths were as follows: 312 under one year old; 184 under five years old; 173 were due to nervous diseases; 170 to consumption; 160 to pneumonia; 120 to heart disease; 87 to acute intestinal diseases; 78 to bronchitis; 75 to diphtheria and membranous croup; 66 to cancer and 44 to typhoid fever.

The Passaic Sewage Problem.—A bill is shortly to be presented to the New Jersey legislature for the building of a great trunk sewer line twenty-six miles long, extending from Paterson Falls to Newark Bay, at a cost of \$6,500,000. The work is necessarily of a State nature, inasmuch as there are parts of five counties and eighteen or twenty cities, towns or hamlets in the lower Passaic sewer district. The commission having the matter in charge, in their report to the New Jersey Sanitary Association, estimate that the population of the valley may reach 1,458,000 in 1930. They refer to the dry summer of 1896, when the river proved a veritable cesspool, and make passing allusion to London, Manchester, Glasgow, Berlin, Paris and other centers of population as grappling with the same difficulties in a strikingly humanitarian spirit.

Some Changes of Interest to New York Physicians.—The new State charter of New York allows the addition of another medical member of the city board of health, making three doctors to two laymen. Meetings are to be held in the main office of "the borough," but there will be a branch office in each borough and as many more as may be necessary. The Board of Public Charities is to be formed much on the same lines, the jurisdiction being slightly changed. One commissioner is to be appointed for New York County, another for Brooklyn and Queens Boroughs, and the third for Richmond. The mayor designates the president. A tardy recognition of the rights of the general practitioner is to be noted. The system of registered physicians, who are to be called by the police in emergency cases, which is now in vogue in Brooklyn, has been adopted for the whole city. If patients are unable to pay the physicians for their services the doctors will be recompensed out of a public fund.

Heavy Death Rate at Havana.—Recent reports from Cuba show that a decimation of the population (estimated at 200,000), has been going on during recent months, and the life loss is really greater than in the summer. Deaths from yellow fever have decreased steadily since the middle of summer on account of the establishment of military hospitals outside of infected towns and because of the cool weather. Enteric fever does not seem to exist to any extent beyond the military hospitals but it appears to be very fatal in those institutions. Deaths from malarial fevers have also increased, and no diminution is reported in the number of deaths from enteritis, dysentery and diarrhea; in fact, the deaths from enteritis have increased largely in the military hospitals. The report shows that the total number of deaths in the city of Havana and the town of Regla during the month of November, from all causes, amounted to 2,317, equivalent to an annual death rate of 139 per thousand inhabitants. In June there were 1,041 deaths, equivalent to an annual death rate of 62.46 per thousand; in July, 1,193 deaths, equivalent to a death rate of 71.52; in August, 1,439

deaths, equivalent to a death rate of 86.34; in September, 1,778 deaths, equivalent to a death rate of 106.68; in October, 2,272 deaths, equivalent to a death rate of 136.32; in November there were 2,317 deaths, equivalent to a death rate of 139. It is evident that the contracted food supply has at last reached that point where no food stuffs are delivered without immediate payment. Beri-beri, which has heretofore been confined to the Chinese population in Havana, is reported to exist to some extent among the natives of the lower class, and it is reported to be spreading in Matanzas. Two deaths from leprosy were reported during the month. These deaths were not reported from the leprosy hospital, but from private residences, and it is no unusual sight to see lepers in the streets.

Argument versus the Proposed Senate Bill for Establishing a National Quarantine System.—Dr. Hermann M. Biggs of the New York City Board of Health has given expression to his views criticising the sanitary scheme laid down in Senator Caffery's well-known bill. It will be seen that Dr. Biggs would minimize the executive powers of the proposed national sanitary body and would exalt its scientific, advisory and educational functions. It is his opinion that the time has come when there should be some Federal supervision through a national board or bureau of health. Such a department should have power to determine the minimum sanitary requirements at all ports of entry throughout the United States and should determine the sanitary regulations relating to interstate commerce and communication when there is danger of the transportation of contagious disease from one State to another. It should be controlled by a board whose members possessed the highest scientific attainments and its regulations should be enforced through an executive officer. Such a national department should have thoroughly equipped laboratories, presided over by bacteriologists and chemists competent to make experimental investigations of the highest order. A prominent feature of the work of such a department should be educational. It should issue from time to time circulars of information on various matters connected with the diagnosis, treatment and sanitary supervision of the various infectious and contagious diseases; on methods of disinfection and on various other matters connected with public medicine. These circulars should be forwarded regularly to the health officers of all cities and towns throughout the United States. The circulars of information which would be issued by it (providing the board controlling it was constituted of men of such character as to give the utterances of the department force) would be accepted by all local medical officers of health, State boards and health officers of maritime ports as the minimum sanitary requirements. The educational value of the work of such a department can not be overestimated. In cases of emergency, at the request of local authorities, such a bureau should be prepared to send experts to advise or assist the local authorities in dealing with any unusual or alarming epidemic. In my opinion the bill which has passed its second reading, and is in committee, in the United States Senate does not at all satisfy the requirements of such a department. Under the provisions of this bill unusual powers are placed in the hands of the Secretary of the Treasury, or, in other words, in the hands of the Supervising Surgeon-General of the Marine-Hospital Service. The Marine-Hospital Service was not designed, nor is it competent, to perform the functions of a national bureau of health. It has the supervision of a large series of hospitals for the care of sick seamen. The duties connected with such work do not in any way fit members of the service to perform those required of a national bureau of health. In Great Britain the Local Government Board exercises powers similar to, but more extensive than, those suggested for this department. In my opinion, under the plan outlined, the establishment of a national bureau would soon result in the adoption of uniform methods and requirements throughout the United States.

MISCELLANY.

The Modern Treatment of Prostatic Trouble. Whatever may be the preferences or conclusions of surgeons regarding a choice between castration and vasotomy, one thing is very certain that after the latter operation the patient will notice a *vas deferens*.

A Recent Appointment.—Dr. Marie Louise Benoit of Lowell, Mass., has been appointed medical interne in the New York State Craig Colony for epileptics at Sonyea. She claims the honor of being the first woman so honored.

Treasured Prescriptions.—Among the archives of the Vatican has been found a collection of copied prescriptions in the handwriting of Michael Angelo. As the artist was much troubled with failing sight during the wane of his life the remedies were intended in all probability for senile cataract.

A Change.—Dr. R. Harvey Reed has accepted the position of superintendent and surgeon in charge of the Wyoming General Hospital, located at Rock Springs, Wyo. This Hospital will be opened for patients about April 1, 1898, and when completed will have accommodations for eighty beds. Dr. Reed will continue with the Columbus Medical Company as one of the associate editors.

A Gift to the New York Academy of Medicine.—At its recent meeting the following nominations were made: Vice-presidents, O. B. Douglas and W. H. Katzenbach; recording secretary, M. Allen Starr; treasurer, H. E. Crampton. The Board of Trustees reported the gift by Mrs. Anna Woerishoffer, of \$15,000 to the library endowment fund and it was decided that this sum be set aside as a special fund to be known as the "Anna Woerishoffer Fund."

Bureau of Medical Literature.—Dr. Carl H. von Klein has opened a bureau of medical literature at No. 243 East Erie Street, Chicago, to furnish medical literature to medical writers on every subject from its earliest history, and from every language in which medicine is written. Dr. von Klein needs no introduction to the profession; he is well known as one of the most accomplished linguists on both sides of the Atlantic. His latest translation of Fischer's "Surgery One Hundred Years Ago," is acknowledged praiseworthy by the best critics. The profession will welcome such a bureau, for through it the busy physician will be able to obtain a little rest, while Dr. von Klein will make his researches and translations. The country practitioner can thus take advantage of the nearly one hundred thousand volumes of medical literature in the city of Chicago, including the libraries of the AMERICAN MEDICAL ASSOCIATION, the Senn collection (which includes the Baum and DuBois Raymond libraries), the Newberry, and European medical journals which are kept on file in the various medical libraries. The Editor of the JOURNAL joins with many others to wish Dr. von Klein much success in his worthy pursuit.

Organized Opposition to Hospital Abuses at New York.—A stormy session was held before the New York City Board of Estimate recently over giving away of the public money to the so-called "private charities" and teaching institutions. Dr. F. R. Sturges was spokesman for the league. He was supported by representatives of the County Medical Society, the County Medical Association and the New York Medical Society. These Societies have appeared annually for several years to oppose such appropriations. They were met heretofore with the statement that the State fixed the amount the city should give. Under a recent law the amount to be paid to each charity is made discretionary with the Board of Estimate. League members fought hardest against the giving of assistance to college hospitals, holding that such institutions receive tuition fees from students and take charity patients, not from benevolent motives, but that they may have clinic patients. The league held that instead of giving so much money to private charities the city

should increase its appropriations for the department of charities, that there might be more public hospitals. League men charged that doctors made personal profit from private hospitals for which public moneys were demanded, and officers of hospitals replied that the doctors who protested represented a political organization. The Sloane Maternity, with which the names of divers millionaires are identified, was among those that were attacked, as also was the Post Graduate Hospital's baby-ward. One institution received over \$300,000, and the total grant to twenty-five beneficiaries was \$1,312,000. And there are still others to be acted upon at an adjourned meeting.

Health Authorities unendowed with Police Powers.—The appellate courts in New York State are quoted as "steadily putting a curb upon the arbitrary and unwarranted exercise of what is known as the police power, in behalf of the health authorities of cities and towns. These officials, not always content with doing what is appropriate to preserve the public health, go far beyond that and interfere inexcusably with property rights." A recent case in New York City furnishes the inspiration of a decision which may bring far-reaching complications in its train. Here the department properly procured an order preventing the use of the property for tenement purposes, on account of its condition. The order went further and directed the destruction of the buildings, although there was no proof that they could not be put to other uses without constituting a nuisance. This the appellate division holds to be wrong, saying that the right to destroy the buildings does not exist, unless they were incapable of being put into such a condition that they would be dangerous to the public health. A lawyer in the case remarked that "exceeding peace had made Ben-Adam bold."

Test of the Army Emergency Ration by Infantry.—Two companies of the Fifth U. S. Infantry were directed by the War Department to make a five-day march from Fort McPherson, Ga., to test the use of the emergency ration. Maj. B. D. Taylor, surgeon, who accompanied the troops, reported that the test of the efficiency of the ration, so far as the men were concerned, was a failure, as it was impossible to be certain that they used it exclusively. One of the company commanders states that the men had been paid the day before starting on the march and thus had the means of purchasing such articles as they desired; and that as they marched through a country abundantly supplied with poultry, milk, butter and eggs, they availed themselves of their opportunities to purchase these articles. Six companies of the regiment, marching over the same ground, were living on the field ration, and had fresh meat and fresh bread nearly every day. Under such conditions it was regarded as hardly to be expected that the men on the emergency ration would live on the same monotonous diet for five days, especially when they were constantly being invited by their comrades of other companies to share their meals. The commissioned officers of the two companies messed together, along with the surgeon, and these lived on the ration exclusively for four days. The surgeon expressed himself as being of the opinion that the ration was amply sufficient, so far as its nourishment is concerned, to sustain life for five days under the strain of the marches made. He found only one man who was able to eat the whole allowance of sixteen ounces hard bread. In fact, all the officers considered that there was an excess of hard bread and pea meal in the ration and suggested a reduction in the quantity. The reports of these officers have been subjected to very unfavorable comment by Deputy Surgeon-General Smart, who conducted the test of the ration made by the First U. S. Cavalry in May last, to whom the reports of the experiment by the Fifth Infantry were submitted. Dr. Smart in his indorsement, which is concurred in by Surgeon-General Sternberg and Commissary General Bell, says:

"These reports show a total misapprehension of the objects of the expedition, and illustrate the necessity for instructing company officers, if the emergency ration is to be of value in times of actual war. The five days' rations, according to the views of the Emergency Ration Board, contain food material sufficient to sustain troops for five days under the maximum strain of war service, and every one who has roughed it on hard bread, bacon and coffee, will acknowledge that there is enough. Troop E, First Cavalry, made a ten days' march in May last on the five days' rations, and the men were in fine spirits and excellent athletic condition at its close. There is no question, therefore, of the ability of five days' rations to sustain men for five days; nor is there any question of the ability of troops to economize their five days' rations so as to make them suffice for a longer period if the officers exercise the necessary supervision over the diet of the men. The experiences recorded in the enclosed reports can not be accepted as in any way a test of the emergency ration. They are, if anything, a test of whether men making light marches could eat and digest in five days what was intended, if need be, to last them for ten days. As might have been expected, they could not. They found the hard bread and pea meal too much for them, but their recommendation that the quantity of each in the emergency ration be reduced, has no value because made in the evident absence of an understanding of why the quantity in the ration was larger than they could eat during their march. The aims of the officers of these commands in making this march as a test of the ration should have been to see that the men lived on the ration, and on the articles of the ration alone, to see that as the men had more than enough at command they did not do themselves harm by overeating, and to see that no part of the ration was destroyed or thrown away, so that at the close of the march a report could have been made of how much of each article had been used under the conditions of their five days march. Another of the objects of a test march by infantry should have been to determine the best way for the soldier to carry his rations. One report says that there is no difficulty in carrying five days' rations, but the best method of packing on the person of the soldier is not specified; while from another report it is gathered that only half a day's ration was carried on the person. Obviously, as the most elementary points connected with testing the value of the emergency ration do not seem to have been appreciated on this march of companies of the Fifth Infantry, the reports of the march have no bearing on the sufficiency or insufficiency of the ration."

Cincinnati.

THE WEEKLY MORTALITY REPORT shows: Still births, 7; zymotic diseases 12; phthisis pulmonalis, 15; other constitutional, 9; local diseases, 57; developmental, 6; violence, 5; under 1 year of age, 20; under 5 years, 32; total, all causes, 104; preceding week, 106; corresponding week, 1896, 120; 1895, 124; 1894, 123.

THE STATE BOARD OF MEDICAL REGISTRATION has been successful in securing the indictment of nine illegal practitioners, and in the case of the State of Ohio vs. France gained a victory in the supreme court by not only having the decision of the lower court affirmed in the matter of the fine imposed, but also the constitutionality of the medical law upheld.

DR. J. B. HOUGH of Lebanon, Ohio was found dead at his home December 3. Dr. Hough was 70 years of age and occupied the chair of chemistry in the Miami Medical College of Cincinnati for a number of years.

THE following half-yearly changes in the staff of the Cincinnati Hospital occurred December 1: Dr. N. P. Dandridge and Dr. E. W. Walker relieve Dr. J. C. Oliver and Dr. Jos. Ransohoff; Dr. E. W. Mitchell relieves Dr. Jos. Eichberg; Dr. C. S. Evans relieves Dr. A. Ravogli; Dr. S. C. Ayres relieves Dr. Geo. H. Good; Dr. W. H. Taylor and Dr. Chas. A. L. Reed relieve Dr. G. M. Allen and Dr. C. D. Palmer; Dr. F. W. Langdon relieves Dr. H. H. Hoppe; Dr. S. E. Allen relieves Dr. Max Thorne; Dr. B. K. Rachford relieves Dr. Allyn Poole, and Dr. Chas. H. Castle takes the orthopedic department.

DR. GILBERT I. CULLEN has returned after an extended tour abroad. He attended the International Medical Congress at Moscow, the Leprosy Congress at Berlin and the French Surgical Congress at Paris.

THE HEALTH DEPARTMENT has just issued a list of all phy-

physicians in Hamilton County who are duly registered by the State Board of Medical Registration, together with the date of their graduation and registration, college, school practiced and residence.

THE DEPARTMENT OF HEALTH has announced that in view of the generally accepted theory of the contagious character of tuberculosis, all cases are to be reported just as other contagious diseases. There is no announcement made, however, which refers to the compensation that the physician is to get for performing this act of precaution for the good of the general public. The Department is also to examine all children who have had diphtheria or have been exposed to it, and they are not to be allowed to return to school until their throats fail to present the Klebs-Loeffler bacillus. The attending physician is to make the examination, the Health Department furnishing the culture tubes and making the culture examination free of charge. In order to carry out the above plan the following rules have been adopted: 1. The culture must be made not less than seven days after the physician has notified the department that the patient has been dismissed. 2. If the examination of the culture is negative the quarantine will be raised in four days from the time of examination. If the culture shows the Klebs-Loeffler bacillus the physician will be informed and another culture must be made in not less than one week after the first culture. 3. In any case where the physician in charge does not desire to make the culture for raising the quarantine the health department will have the culture made at the end of two weeks after the patient has been dismissed.

A CASE OF TENIA ECHINOCOCCUS or hydatid liver has developed here and has aroused considerable interest. Several large cysts have developed and the presence of the parasite has been demonstrated. The disease is a very rare one in this country, Osler being able to collect the records of but eighty-five cases that have occurred in the United States and Canada up to the present time.

Philadelphia.

THE STATE MEDICAL BOARD OF EXAMINERS AND LICENSERS held its winter session during the week ending December 18. There were 103 applicants, out of which number 34 failed to receive the average permitting them to receive the certificate and license. Among the applicants were some holding diplomas from institutions in Germany, England, Italy, Russia and France, but the majority as usual were graduates of last spring from Pennsylvania schools. Thirty of the candidates were recent graduates who had failed to pass at the last examination. Unfortunately for them, the majority of those rejected were also from this group, which seemed, at least in three instances, to prove conclusively the inadequacy of the test offered by the final examinations at the colleges. Some of them were totally unfit, as may be inferred from the following specimen replies: To the question, "What is metabolism?" one man replied: "It is the perasstasis of the blood," and as to the characteristic changes and clinical appearances occurring in tubercular arthritis evoked the following: "The liver and kidneys do not function properly and the skin is covered with lumps." Among those who passed with distinction was one whose professional character and personal worth would have been gladly acknowledged by the Board by granting the license without requiring him to submit to the indignity of an examination with this year's graduates, and, indeed, a motion to omit the examination in his case was entertained by the Medical Council, but it was found that the law was mandatory and ironclad, permitting no exceptions to be made whatever. This was Dr. W. L. Rodman, who has recently come here from Louisville, Ky., to accept the chair of the Principles of Surgery and Clinical Surgery in the Medico-Chirurgical College, and who has been warmly welcomed to the ranks of the profession in this city.

THE ACADEMY OF SURGERY met December 6 and elected Dr. Ewing Mears president to succeed Dr. Thomas G. Morton, who had served for three successive terms. A death during

the administration of ether was reported by Dr. T. G. Morton at this meeting. The patient was about 60 years of age and had been admitted to the Pennsylvania Hospital for gastric disorder of a year's standing, malignant disease being suspected; pyloric stenosis and dilatation of the stomach was known to exist. Ether was administered in order that an exploratory operation might be made. The patient took the anesthetic badly and there were such convulsive movements of the diaphragm and abdominal wall that it was impossible to close the wound after the section had disclosed an inoperable fusiform cancer of the pylorus and infiltration of the stomach wall. A few drops of chloroform were given, while the ligatures were rapidly applied, but the patient vomited freely a thin, gruel-like fluid and shortly afterward stopped breathing and all efforts at resuscitation failed. The autopsy by Dr. Cattell, the coroner's physician, showed that suffocation had caused death, the bronchial tubes being completely filled with the same thin tenacious fluid which was found in the stomach. Dr. Morton pointed out that in cases of dilated stomach, abstinence from food on the day of operation is not sufficient and he advocated washing out the stomach in such cases as an important precaution to be taken before the administration of ether.

AT THE December meeting of the College of Physicians, Dr. John B. Deaver read a paper entitled "X-Ray Pathology of Fractures about the Elbow," which he illustrated with the aid of the stereopticon.

THE OBSTETRICAL SOCIETY held its meeting December 2. The more important communications were one by Dr. Joseph Eastman of Indianapolis on "The Question of Pelvic Support," and one by Dr. Joseph Taber Johnson of Washington, D. C., on "The Best Way of Treating Pus Collections in the Pelvis; the Abdominal versus the Pelvic Route." After a discussion of the subjects by Drs. J. M. Baldy, Charles P. Noble, W. E. Ashton and others, the Society attended a reception in honor of its guests, at which Dr. E. E. Montgomery presided as the host, at the University Club.

A CHARTER has been granted for a new hospital for contagious diseases, which is to be called the "Health Protective Hospital for Contagious Diseases," in honor of the Woman's Health Protective Association, which has been actively engaged in sanitary work for several years in this city. The announcement has been made that a site has been secured by the purchase of property at Twenty-second Street and Lehigh Avenue, Philadelphia, opposite the Municipal Hospital. The necessity for a pay hospital for such diseases as scarlet fever and diphtheria has been acknowledged for several years, and its establishment has been advocated especially by the late Dr. William H. Ford, president of the City Board of Health; Dr. W. M. Welch, chief physician of the Municipal Hospital, and by Dr. Benjamin Lee, secretary of the State Board of Health. The work has been accomplished by the labors of a joint committee from the Woman's Association above named and from the Philadelphia County Medical Society, the members of the latter being Dr. J. Madison Taylor, chairman; Drs. Edwin Rosenthal, George M. Gould, James Tyson, Frederick P. Henry and Edwin E. Graham. The committee has had weekly meetings for nearly two years, the scientific work and plans being in charge of the medical representatives, while the active labor of providing funds was accomplished by the women representing the Health Protective Association.

THE DENTAL SCHOOL or Department of the Medico-Chirurgical College is now in full running order and is equipped with the latest appliances, including electric lathe and motors.

THE LAST meeting of the Medical Club was devoted to a reception in honor of Prof. Howard A. Kelly, M.D., of Johns Hopkins Hospital.

CHARTER FOR A FAITH-CURE CORPORATION REFUSED.—In Court of Common Pleas, No. 2, Judge Pennypacker recently handed down an opinion in which he refused to grant a charter to the "First Church of Christ Scientist" and delivered an important ruling as to the reasons why the incorporation of a

church, having the practice of faith-cure as one of its objects, is contrary to the laws of Pennsylvania. The chief criticism of the proposed charter was that it conflicted with the act regulating the practice of medicine and requiring all candidates for license to successfully pass an examination before the State Board of Examiners and Licensers, and to have had a previous training of four years in certain prescribed studies, whereas the proposed charter would confer the authority upon the so called church to empower any of its members to treat the most serious diseases although not qualified by the proper course of medical studies or duly licensed by the State Board. "It is quite clear" said the Judge, "therefore, that what is proposed is much more than a church since there is besides to be established a system for the treatment of disease, to be carried into effect by persons trained for this purpose who may receive compensation for their services."

THE STANDARD MEDICAL HISTORY OF PHILADELPHIA, compiled by Frederick P. Henry, M.D., has just appeared in a handsome imperial octavo volume, which is published by a Chicago firm and is for sale by subscription only. It is freely illustrated and contains much valuable historic material of more than local interest, especially with regard to the origin and early struggle of our medical institutions.

THE PHILADELPHIA MEDICAL JOURNAL, a new \$3 weekly, edited by Dr. Geo. M. Gould, issues its first number Jan. 1, 1898. As it is not controlled by any publishing house or commercial corporation, it may be expected to be thoroughly independent and to serve no interests other than those of the medical profession. It is published by the Philadelphia Medical Publishing Company, representatives from the leading medical schools being members of the Board of Trustees, who are to be elected annually, and to whom is entrusted the management of the affairs of the Company.

Detroit.

AT THE regular meeting of the Detroit Medical and Library Association, held December 6, Dr. George Duffield presented a paper entitled "Guaiaicol in the Treatment of Typhoid Fever." The author first took up the internal administration of the drug. The object is the introduction of an antiseptic drug into the intestinal canal, and the author finds that guaiaicol is better than any other remedy for this purpose. He said: "I have never noticed any antipyretic effect when the medicine is administered internally. I give it for its antiseptic properties alone, and I am sure that I accomplish the end sought, because the stools are redolent with the characteristic odor, showing that the medicine must have passed the diseased surfaces as guaiaicol and rendered the part aseptic by its presence there. When the stomach is so irritable that the pure guaiaicol can not be administered, then we have recourse to the carbonate. I have used Woodbridge's method for several years, and believe his plan is successful in producing an aseptic condition of the intestinal canal, but it is slow, and I believe his plan can be modified so as to produce better effects. I use calomel with or without podophyllin, at first every hour or two until the bowels are thoroughly moved and the flow of bile, nature's antiseptic, is established. Saline waters increase the effect of these drugs and the effect of the guaiaicol is augmented." The author next took up the external application of guaiaicol. The Doctor stated that the best possible point for the application is on the skin of the abdomen over the ileocecal valve. After thoroughly washing the surface with soap and water, 15 to 30 minims of the liquid is dropped upon the skin and gently rubbed in by an attendant for ten minutes and the area is then covered with cotton and oil silk. The dose should not exceed 30 minims, for often such application is followed by great depression, profuse sweating and sharp chills or other symptoms of collapse. Its effect, when properly applied in the proper dose, is to cause profuse perspiration, the temperature declines and continues to descend for three to four hours. "The pulse grows full and strong and its rapidity lessens in proportion to the reduction of the temperature; the patient shows no signs of cyanosis and invariably says he feels 'first class.' I have noticed that when it has been applied frequently for three or four days, in typhoid fever, a decided reaction takes place and the temperature gradually declines and reaches normal at an earlier period than it otherwise would have done. This treatment can be used with the Woodbridge method to advantage, as something else beside the tablets, which are necessarily slow in their action, should be used to reduce high temperature." No blistering or inflammation of the skin is produced when the drug is applied. "That it is far superior to the cold bath in the treatment of typhoid fever, I believe. It is easy to apply and is safe and efficient."

HEALTH REPORT for week ending December 18: Deaths 77, under five years, 30. Births, male 40, female 36. Contagious diseases, diphtheria 15, scarlet fever 62. Deaths from diphtheria 2, from scarlet fever none.

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the two weeks ending December 24, 1897.

Surgeon A. C. H. Russell, detached from the "Lancaster" and ordered home on waiting orders.

Medical Inspector J. G. Ayers, ordered to duty at the navy yard, Portsmouth, N. H., January 17.

Medical Inspector J. B. Parker, detached from the navy yard, Portsmouth, N. H., and ordered to duty as member of the naval medical examining board, Washington, January 22.

P. A. Surgeon T. B. Bailey, unexpired leave revoked, and ordered to the Washington navy yard.

CHANGE OF ADDRESS.

Banton, W. C., from Chicago to 210 Grand Av., Waukegan, Ill.

Burwell, W. M., from Chicoteague Island to Wallis, Va.

Beavis, A. J., from 110 15th St. to 1429 Pearl St., Denver, Colo.

Cobb, J. O., from New York, N. Y., to U. S. Marine Hospital, Detroit.

Cresswell, G. W., from Arvada, Wyo., to 8 De Kalb St., Chicago.

Cline, L. C., from 42 E. Ohio St. to 222 N. Meridian St., Indianapolis, Ind.

Cook, J. F. D., from Clark to Langford, S. D.

De Witt, J. P., from Pierce to 306 S. Cleveland Av., Canton, Ohio.

Hart, A. C., from 1170 Market St. to Claus Spreckel's Bldg., San Francisco, Cal.

Lawbaugh, A. L., from Opechee to Calumet, Mich.

McConnell, J. W., from 1909 Chestnut St. to 225 Fairmount Av., Philadelphia, Pa.

Meany, W. B., from 3907 W. Bell Pl. to 1608 4th Av., St. Louis, Mo.

Platon, L. A., from Cooperstown to Valley City, N. D.

Quigley, J. M., from 218 Powell St. to Waller and Clayton Sts., San Francisco, Cal.

Reed, R. H., from Columbus, Ohio, to Rock Springs, Wyo.

Riley, E. A., from Starfield, Mo., to Hoyt Kas.

Terry, Jr., M. C., from Brighton, Iowa, to Fort Shaw (via Sun River), Mont.

LETTERS RECEIVED.

Atkinson, W. B., Philadelphia, Pa.; Ashmead, Albert S., New York; American Therapeutic Co., New York.

Burr, C. B., Flint, Mich.; Barnham, F. G., Los Angeles, Cal.; Bulkley, L. Duncan, New York; Boteler, W. C., Washington, D. C.; Bell, F. A., Dallas, Texas; Beale, G. E., Freehold, Pa.; Brown, Margaret (Mrs.), Stratford, Canada; Ball, M. V., Warren, Pa.; Bittick, S. G., Henrietta, Texas; Battle & Co., St. Louis, Mo.; Burnham, H. B., Manchester, N. H.; Bryan, Charles, Corn, W. Va.; Baird, James, Evanston, Ill.

Coleman, W. F., Chicago; Crane, A. W., Kalamazoo, Mich.; Clarke, Augustus P., Cambridge, Mass.; Chas. Truax, Greene & Co., Chicago; Cleveland, Theodore P., Baltimore, Md.; Chicago Eye, Ear, Nose and Throat College, Chicago; Chicago, Milwaukee & St. Paul Railway Co., Chicago; Colville Bros. & Perry, Galesburg, Ill.; Concanan, James J., New York.

Deaver, John B., Philadelphia, Pa.; Dow, Daniel C., Cambridgeport, Mass.

Elgin Milkline Co., Elgin, Ill.; Elliott, H. G., New York; Eagleson, J. B., (2), Seattle, Wash.

Friend, Samuel H., Milwaukee, Wis.; From, F. J., Templeton, Iowa; Fougere, E. & Co., New York; Fisher, G. C., Ann Arbor, Mich.; Farrington, John M., Binghamton, N. Y.; Finley, G. W., Harmony, Ind.

Garber, J. B., Dunkirk, Ind.; Griffith, J. D., Kansas City, Mo.; Gould, George M., Philadelphia, Pa.

Haldenstein, I., New York; Henry Pharmacal Co., Louisville, Ky.; Henry, R. S., Charleston, W. Va.; Haughton, R. E., Richmond, Ind.; Horlbeck, H. B., Charleston, S. C.; Hare, H. A., Philadelphia, Pa.; Hayden, A. M., Evansville, Ind.; Harris, J. J., St. Louis, Mo.; Hunsberger, J. Newton, Skipack, Pa.; Howe, Lucien, Buffalo, N. Y.; Hygela, The, Citronelle, Ala.; Hobart, John P. (2), Cincinnati, Ohio; Hull, W. H. H., & Co., New York; Hummel, A. L., Adv. Agency (2), New York.

Imperial Granum Co. (2), New Haven, Conn.

Jefferson Medical College, Philadelphia, Pa.

Kirch, F. A., Toledo, Ohio; Kelley, Maus & Co., Chicago.

La Rue, F. G., Hampton, Ky.; Library Surgeon General's Office, Washington, D. C.; Larned, E. R., Joliet, Ill.; Little, J., Bloomington, Ill.; Langdon, F. W. (2), Cincinnati, Ohio.

Merrick, M. B., Passaic, N. J.; Moore's Newspaper Subscription Agency, Brockport, N. Y.; Manley, Thomas H., New York; Murfree, J. B., Jr., Murfreesboro, Tenn.; McIntosh, J. M., Connorsville, Ind.; Middlebrooks, J. D., Bryans Mill, Texas; McClure, Theo. R., Lansing, Mich.; MacPherson, F., Dunlap, Mo.; McIntosh Battery and Optical Co. (2), Chicago.

Newbecker, Minerva M., Asylum, Neb.; Newell & Heldman, Chicago; Nutt, G. D., Williamsport, Pa.; Norwich Pharmacal Co., Norwich, N. Y.; Oakland Chemical Co., New York; Od Chemical Co., The, New York.

Parke, Davis & Co. (2), Detroit, Mich.; Parker, W. Thornton, Groveland, Mass.; Plummer, J. W. V. R., Key West, Fla.; Powell, Thomas, Los Angeles, Cal.; Post, S. A., Weston, W. Va.; Powell, R. H., West Milford, W. Va.

Rossiter, F. M., Battle Creek, Mich.; Roberts, William, Fort Adams, R. I.; Rowe, Thomas C., Coal Bluff, Ind.; Ramsay, R. T., London, Ky.; Ring, E. P. C., Philadelphia, Pa.; Rosenthal, Edwin, Philadelphia, Pa.; Russell, E. H., Bluffdale, Ill.

Segur, Gideon C., Hartford, Conn.; Sullivan, T. J., New Frankfort, Mo.; Stallman & Fulton, New York; Simpson-Martin, J. M., Massey, Texas; Spivak, C. D., Denver, Colo.; Stewart, Douglas H., New York; Struthers, A. D., Bedford, Quebec, Canada; Savage, G. C., Nashville, Tenn.; Shoemaker, John V. (2), Philadelphia, Pa.; Schwab, L. W., Chicago, Ill.; Sauder, Enno, St. Louis, Mo.; Scott, J. B., Hamilton, Ohio; Scott, N. Stone, Cleveland, Ohio; St. John, Leonard, Chicago; Sinkler, Wharton, Philadelphia, Pa.; Smith, A. E., Utica, Ohio; Smith, D. C. M., Richland, Kas.; Smith, Q. C., Austin, Texas; Smith, Kline & French Co., Philadelphia, Pa.; Smith, Frank Trester, Chattanooga, Tenn.

Tyree, J. S., Washington, D. C.; Trannweiler, S., Merchantsville, N. J.; Tuley, Henry E., Louisville, Ky.

Vande Roovert, J. P., Chicago; Van Nostrand, D., Co., New York; Way, J. Howell, Waynesville, N. C.; Wetherill, H. G., Denver, Colo.; Woodbury, Frank, Philadelphia, Pa.; White Rock Mineral Spring Co., Waukesha, Wis.; William Publishing Co., The, New York; Weaver, W. H., Chicago; White, F. D., Limestone, Me.; Wolfstein, David I., Cincinnati, Ohio; Wandless, Henry W., Dallas, Texas; Würdemann, H. V., Milwaukee, Wis.

The Journal of the American Medical Association

VOL. XXX.

CHICAGO, ILLINOIS, JANUARY 8, 1898.

No. 2.

ADDRESS.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Physiology and Dietetics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY AUGUSTUS P. CLARKE, A.M., M.D.
CAMBRIDGE, MASS.

The physiology of the various structures of the organism and the choice of the pabulum best adapted to their conservation are subjects that should command our most careful consideration. Formerly when disease was regarded as an entity and a visitation of an offended deity, only little, of course, could be expected to be achieved by dietetic measures. Success that could be obtained, however, by treatment of disease through a change or a restricting of the diet is by no means a modern discovery; the medieval and the ancient writings on medicine reveal many references to the subject. Thus the works of Hippocrates, the "Father of Medicine," show that he was not unacquainted with the evil effects arising from an unwise selection of articles of diet; he speaks of the enervation that results to the constitution from abstinence of food. Knowledge of the fundamental principles of dietetics is essential for the conducting of the cure of disease. There is no question that many morbid processes can be greatly modified by adopting a strictly regulated system of diet. It is largely through the researches made in physiologic chemistry that much of our knowledge has been obtained. Before such results had been acquired the methods of practice were merely theoretic.

One serious mistake that is often made is in prescribing articles of diet without having sufficient data for determining the needs of the organism. There should always be kept in view the importance of obtaining in each individual case a definite knowledge of the proportion that the ingesta bear to the egesta of the system. For ascertaining this relation, the habits and surroundings of the patient should be considered. It is evident that a person who is accustomed to sedentary occupations requires a more restricted diet than one who spends a large proportion of his time in active pursuits in the open air. An increase of weight is not always an indication that the selection of the food has been wisely made, nor, on the other hand, is a diminution of the measurements of the organ a sign that the food is ill-adapted to the needs of the body. The question that should be most carefully considered is whether the food has been sufficient to meet the demands of the normal excretion. The habit of introducing into the system agents that tend to lessen the metamorphosis or waste of tissue should not be overlooked in deciding as to the relative merits of different articles of diet to be employed.

Some physicians are inclined to prescribe, in their routine practice, the kinds of food that have appar-

ently met their own fancied individual needs. Such a course should be looked upon as most unscientific. No class of foods, whether they be of beef, mutton or of fowl, or even of fish, should be selected in preference to all others for the prevention or cure of disease. In deciding what should be taken, reference will have to be made to the analysis of the excreta to ascertain what products have been normally voided, and what proportion of the water and of the chemie elements, carbon, hydrogen, oxygen, nitrogen, and of the sulphates, phosphates, chlorids, potassium and sodium has been eliminated. An examination should be made of the effete matter as comprised in the term carbon dioxid and certain forms of ammonia that are given off through the respiratory processes; the necessity of such investigation should be particularly borne in mind when called to the treatment of those cases in which the lungs have become the disease center. The urinary and perspiratory elements of excretion should also be examined. There can be no doubt that the exhausting nocturnal hyperidrosis accompanying tuberculosis is due to poisonous products that are determined to the lung tissue for elimination; doubtless such a sequel is often superinduced by the failure of other emunctories of the organism.

The utility of a diet's embracing the proteid elements to be administered in many forms of the disease should demand attention. In order to observe the effects of such ingesta the metabolic force of the living cells should in particular cases be measured by actual experiment. There are unquestionably varying degrees of metabolism as possessed by different individuals. The most important feature of the results of indulging in an excessive use of the proteid elements of diet is, notwithstanding that a condition of nitrogenous equilibrium prevails, the tendency to the production of podagria and other allied affections. The system when once brought under the influence of such a dyscrasia becomes readily the center of other diseases. Chronic inflammation of the kidneys is liable to ensue, so, also, are certain forms of interstitial hepatitis; iritis and even meningitis are not infrequent accompaniments of a gouty diathesis. Inquiry regarding the effects of the continual use of carbohydrate food will often have to be made.

The theories that are entertained by physiologists can not always be depended upon as affording facts sufficiently comprehensive for guiding the practitioner in his daily work. Much has been said against the use of starchy foods for the general diet; I apprehend, however, that many experiments that have been made on dogs for the purpose of settling certain questions in regard to the effects on the system of many kinds of food, should be received with some misgivings. Carbohydrates, as is well known, are liable to induce dyspepsia and other gastric troubles; the unpleasant effects of the employment of amylaceous foods may be obviated by a more free use of water. Starch, it

must be remembered, is largely composed of carbon dioxid and water. To facilitate its more rapid decomposition into its ultimate elements, water at the temperature of the body is essential. The chlorophyll or the green coloring matter of plants, that manifests such peculiar action in the decomposition of carbon dioxid and in fixing the carbon in new structures in the form of new compounds, owes its potency in some measure to the aqueous element with which it is always associated.

In establishing what should be a proper diet, many factors will have to be taken into account. Age, habits, exercise, climate, temperature, altitude, strength and perhaps sex, are conditions that must go far toward determining what should be the individual diet of the patient. As said before, a proper balance between the ingesta and the egesta should be maintained. For brainworkers food that is readily assimilable should be taken; the same should be prescribed for invalids.

In the endeavor to reduce excessive obesity by substituting or replacing, almost entirely, the proteids for the carbohydrates, the fact should not be overlooked that there is danger of setting up urinary troubles and of causing vesical calculus, renal disease and contracting kidney. These results by such change in diet have occasionally occurred in my practice. Of the proteids (albumin, casein, myosin, gluten, legumen, etc.) the chief in flesh diet is myosin associated more or less with globulin, serum, albumin, gelatin, elastin and hemoglobin. These are all originally obtained by the animal from the products contained in nitrogenous grasses, herbs and plants.

The question is often asked, why can not man by increasing his knowledge through scientific investigation make a wise and judicious selection of vegetable proteids that will satisfy his real demands for nourishment without having to resort to the consumption of animal food? I might here remark that though the wages of the peon workman of Mexico are ridiculously cheap, about three bits (thirty-seven cents) a day, he is able, on account of the climate being most congenial to his nature, to earn in twelve days, as it has been estimated, enough to meet the actual requirements as regards the necessities of life for the rest of the year. "He does not eat," says Charles H. Lummis (*Harper's Monthly*, March, 1897), "much meat, nor does anyone except a stupid in that climate." Observations made during my recent visit in Mexico tend to confirm the truth of the above statement. Reference to the attainments of the early inhabitants of Mexico opens up for consideration some very important questions in regard to diet. The ancient Mexicans in their habits and acquirements were unlike in many respects those races of the Orient. If they were ignorant of the advantages to be derived from the use of cereal grains they were unacquainted with the nutrient properties of milk and with pastoral pursuits. The food of these early people must have consisted for the most part of fruits, plants, honey, fish and the juice of the maguey. Meats, even of the lighter grades, were merely incidental to their dietary list.

In considering further the question in regard to the necessity of the consumption of animal food for the growth and preservation of the races, it should be said that the ox, the sheep and the other animals whose flesh is esteemed the most essential for the support of mankind, do not derive their nitrogenous compounds by the consumption of other animals;

they obtain such properties merely by the ingestion of grasses, herbs and other elements of the vegetable kingdom. The eating of so much food as the present American people are accustoming themselves to can but be regarded as a more slothful way of obtaining their necessary nitrogenous sustenance and must, therefore, eventually tend to the deterioration of the present inhabitants. A little more activity put forth in the search among the vegetable products for food necessary for the preservation and development of the races of our clime would undoubtedly facilitate the excretion of effete matter and establish a proper balance between the functions of assimilation and excretion.

In the hot climate of India the teachings of the Brahmins forbid the killing of animals for the consumption of their flesh. Many animals in that country are regarded as sacred or as containing the spirit of some departed monarch or chieftain. Perhaps the belief in the creature having such a possession was originally encouraged as a sanitary measure to prevent the indiscriminate use of the diet of flesh. In conversation some time since with a learned Brahmin who was visiting this country I learned that most of our Christian missionaries to India indulge freely in the use of animal food, and thus by persistently refusing, in the choice of their food, to adopt the prevailing custom of the higher castes finally fail to become acclimated and so are compelled after a few years' residence to leave the country. Suffering from boils, abscesses and internal disorders often hastened or superinduced by an over-stimulated diet is not, he said, an uncommon occurrence among these "Soldiers of the Cross." I am by no means an advocate of the exclusive use of a vegetable diet, but I feel confident, nevertheless, that before the advantages of many different articles for varying conditions can be established, many pet theories will have to be abandoned and an investigation carried out on a more scientific basis than heretofore attempted will have to be undertaken.

In connection with the functional activity of the several parts of the human organism and the food best adapted for their conservation there are, as said before, many modifying factors that should be taken into consideration. Prominent among them is the variation of the hematosis that is caused by high altitudes. Man can become accustomed to the influence of elevated centers; when long subjected to the controlling forces of the higher levels his fluids become more concentrated, his respiration and circulation are accelerated and the deficiency of oxygen is compensated for by the increased activity of sanguification.

It has come to be more recognized that the presence of pure oxygen exercises a most potent influence on animality. During the early geologic ages, according to T. L. Phipson, nitrogen almost entirely constituted the earth's atmosphere. As vegetation advanced oxygen was more freely disengaged from the deeper centers and the anaerobic cellulæ underwent a modification: the anaerobic organisms assumed more the nature of aerobic bodies until the nervous cerebrospinal axis reached the development under the forms in which it is now represented. Man may, however, feel the want of ingesting for his aliment a large proportion of the nitrogenous element, but this craving, it must be conceded, is in no small measure the outcome of atavistic tendencies.

Those who deny the development of man from the lower forms of animal life, but hold strictly to the view that when he did first appear he was invested with organs not unlike those which he now possesses and that the shape and condition of his incisor-teeth were given him by an all-wise Creator for the purpose of fitting him, in part at least, for partaking of flesh, should remember that according to the Mosaic account man's sphere of activity was first limited to the confines of a garden, where he was allowed to eat, not of flesh, but of every fruit with the exception of one that was in the inclosure; that it was only after his expulsion from that favored spot that mankind through his hardness of heart was, at his own expense and suffering, granted many indulgences. Nitrogen as a constituent of the air serves merely as a diluent. As a component part of the tissues for the highest or even for the average type of man, who can say that its presence is absolutely essential?

There are still many unexplored fields in which physiologists can carry on work to great advantage. Research, to be of value, can only be made by careful experimentation. Those schools that are encouraging original investigation in this line of inquiry will receive the largest returns. In conducting experiments many problems should be taken into account; the influence of the temperature on the form of muscle curve, the peculiar features of electrotonus, the rhythmic action of the heart, the duration of its beats, its compensatory pause and other phenomena that are exhibited should be carefully studied. Observations thus made should not be looked upon as conclusive as to results that will invariably follow in every individual experiment, for the functions of animals, even of the same class and under what would appear to be precisely the same circumstances and conditions, are continually undergoing change and modification in development. It is only by repeating experiments many times that an average result can be obtained. The importance, therefore, of the study of the morphology of the protocoecus, the ameba and of the paramecium and their reaction to certain forms of electricity and individual stimuli will thus be more readily appreciated.

THE HISTORY OF THE SECTION OF PHYSIOLOGY AND DIETETICS.

The introduction of the Section of Physiology and Dietetics into the AMERICAN MEDICAL ASSOCIATION, though of a recent date, was a wise measure. It was done in response to the necessity of correcting many errors and misapprehensions in regard to the importance and value of many different kinds of food that are employed in the care of hospital and private patients and are consumed by the people generally. The place in which any work of importance was first accomplished was at the meeting of the ASSOCIATION at Detroit, Mich., 1892. An address on "Physiology" was delivered by the chairman, C. H. A. Kleinschmidt, Ph.D., M.D., Washington. "Epithelia" was the title of a paper by Ephraim Cutter, M.D., LL.D., New York. The other papers were: "The Marine Hospital of Boston," by George W. Stoner, M.D., Surgeon U. S. Marine-Hospital Service; "Food and Hygiene of All Ages," by John M. French, M.D., Milford, Mass.; "Medical Food Ethics, Now and to Come," by E. Cutter, M.D., LL.D., New York; "United States Army Rations and Military Food," by Capt. Charles E. Woodruff, M.D., Assistant Surgeon U. S. Navy;

"United States Naval Rations," by C. A. Siegfried, M.D., U. S. Navy; "Diet, in its Relation to the Treatment and Prevention of Disease," by Augustus P. Clarke, A.M., M.D., Cambridge, Mass.; "The Paddock Pure Food Bill" was brought up and discussed. The publication of the above mentioned papers and a report of the meeting by the Secretary, Dr. Ephraim Cutter, are found in the columns of the JOURNAL, 1892.

The officers of the Section in 1893 were: I. N. Love, St. Louis, Chairman; Ephraim Cutter, New York City, Secretary. The officers of the Section in 1894-95 were: E. H. Woolsey, Oakland, Cal., chairman; C. G. Chaddock, St. Louis, secretary; Executive Committee, I. N. Love, St. Louis; W. T. Bishop, Harrisburg, Pa.; Ephraim Cutter, New York. The program comprised: Address of Chairman, E. H. Woolsey, Oakland, Cal.; "On Food and Thrombosis," by Ephraim Cutter, New York; "Physiologic Treatment of Tuberculosis by Injection of Serum," by Paul Paquin, St. Louis; "Vital Resistance to Disease," by G. W. Finley, Harmony, Ind.; "Researches in Rapid Photography by Means of Edison's Kinetograph, and the Animated Reproduction by the Kinetoscope; Showing also by this Method the Present and Future Possibilities of Taking and Reproducing Certain Animated Physiologic Movements of the Larynx, Heart, Intestines, etc., with an Historical Account of Fifty Years of Photography," by J. Mount Bleyer, Naples, N. Y.; "The Influence of Atmospheric Electro-Barometric Oscillations," by John North, Toledo, Ohio; "The Physiologic and Pathologic Effects of Electricity, with Some Results of Practical Experience with Electricity," by E. H. Woolsey, Oakland, Cal.; "The Physiology of Instinct," by C. G. Chaddock, St. Louis; "Remarks on Test Meals," by Henry Salzer, Baltimore, Md.

The officers for 1895-96 were: H. Bert Ellis, Los Angeles, Cal., Chairman; Henry Salzer, Baltimore, Secretary. The members of the Executive Committee were: I. N. Love, St. Louis; E. H. Woolsey, San Francisco; H. Bert Ellis, Los Angeles; Augustus P. Clarke, Cambridge, Mass., chairman; Ephraim Cutter, New York, secretary.

This year an effort was made by your chairman and secretary to induce the leading members of the ASSOCIATION to make contributions to raise the standard to a footing with the other departments. How well they have succeeded in this regard it is not for them to say. It is to be hoped that this important branch of medicine will hereafter find representatives who at all times will gladly contribute to its support.

DISCUSSION.

Dr. EPHRAIM CUTTER of New York—The history of this Section goes back to 1889 at least, for that year it was announced on the program at Newport, a special room was selected and assigned to it beforehand and arrangements were made for the solar projection of the morphologies of foods. Considerable money was spent by the Secretary, but another Section wishing the assigned room, the authorities withdrew it and furnished another room where the sun could not be had, and this was such a damper that not a paper was read, nor the three cases of men cured of Bright's disease by food exhibited! The whole thing failed because faith was not kept by the Committee of Arrangements.

In 1890 this Section was on the program at Nashville. E. A. Wood, Chairman; E. Cutter, Secretary. The Committee of Arrangements unwittingly failed to give proper accommodations for solar projection. A room was assigned for the meetings of the Section but when we went to take possession at the proper hour we found it occupied by some 150 to 200 young law students listening to a lecture from a professor! The Chairman was so disgusted that he would not do anything more, save to give an admirable address on "Food" in one of

the general meetings, which was enthusiastically received and applauded to the utmost.

In 1891 the Secretary could not attend and can not report. This brings the history down to Dr. Clarke's report.

Our honored Chairman insists that complex foods must be given to the sick for cure of disease; in other words that there must be variety. With no disrespect to him, permit me to say that when man comes into the world normally he has but one food, milk; that he thrives wonderfully on it; that every tissue and organ not only thrive but grow and increase; that air is food and air is eaten twenty times a minute during life without change; that the writer has found in some diseases the best results with one food and that changing from one to multiple foods has done harm; further, that the cure is wrought by nature or the Divine power, being furnished with the fewest foods that can furnish material for all tissues.

□ What makes babies sick as a general rule? Too many foods. If a healthy babe has a healthy breast milk in abundance, other things being equal, it will remain healthy. Vegetarians can not deny that one animal food is the normal food of man at his birth. I do not believe it is necessary to have different foods for different diseases as a rule, according to my experience. I wish doubters would try living on different foods singly and thus learn their action and more about disease than can be learned otherwise. The AMERICAN MEDICAL ASSOCIATION ought to institute such experiments in the many biologic laboratories of the continent.

PROBLEMS IN FEEDING SCHOOL CHILDREN.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY HORACE P. MAKECHNIE, M.D.
SOMERVILLE, MASS.

When the plebeians had seceded from Rome, the story of the stomach and members was related as an inducement for them to return. Today we need to have the story retold and our attention called anew to the importance of the stomach as related to all the other organs. So far as our school children are concerned, our physicians are well aware of the facts, which therefore need not be demonstrated. Many years ago, while teaching, I noticed that quite a percentage of children who had been sent to school very young and had been kept there continually became very dull. They would not study nor learn as bright active children ought. I used to say they were school hardened.

Since I have practiced medicine I have been consulted by quite a number of school children who had dyspepsia which was due to a lack of nourishment. What! starvation around tables loaded with food? Yes, that is just it. We do not get our best dinners at Delmonico's, but at some lonely farm house after a day's hunting or fishing. The best dinner I ever ate was a simple vegetable hash after a day's hunting. No epicure ever concocted a dinner like that.

Fashion says that the first course should be soup. The first course should be a ray of sunshine, a breath of fresh air and a dash of exercise flavored with amusement. Most people think when they have supplied an abundance of food for their children, three times a day, that is all as to feeding. When we manage a furnace we know that even to put the coal on is not enough. We may smother the fire with the fuel, or it may be clogged with debris. The drafts and dampers have to be attended to. I grant that our school children have food enough and, in the main, good food, but are they nourished? It is not merely a question of brain cells, but of every cell in

the body. Do we turn out from our schools robust men and women? What should we do but for the poor country schools to send us brains and muscle and push? The idea of a child sitting still six hours a day in order to learn a few uninteresting letters! Let us suppose a child gets up and eats breakfast, what course would you pursue so that he would eat a proper dinner? I mean eat in its broad sense, so that every cell would be fed. Would you send him to sit in a chair, hard and perhaps ill-fitting, for three hours? Would you have him attend to matters that would call the blood especially to the brain? Yet that is what we do with our children year after year. I wish to call attention especially to our high school children. The breakfast comes before they have fairly shaken off sleep and the dinner after a long fast. They may have a lunch. They are not in a mood to properly avail themselves of it. Would any good authority on feeding advocate such a method?

We can not afford to systematically starve our children even by an indirect way, even in a mild degree. Besides, we defeat our whole object. Who has not wondered at the number of men that have poured in from the country and taken the best positions away from our city boys? Who has not wondered at the small and decreasing size of American families, especially in cities? The demand for longer vacations shows that people are sensible of an evil although they have not formulated it. Chain a child to a chair by a teacher's authority for three hours and then expect him to eat. No, you have starved him as surely as though you had deprived him of food. The muscle has not thrown off the old and made ready for the new. Every organ, except perhaps the brain, has shared the same fate. Then, wherefore the eating? Wherefore the proper growth, the nervous energy? If we are not giving our boys and girls the best advantages for assimilating food, is it not worth while to do so? Shall we get stronger, better developed, more energetic, better educated children, better citizens? I believe we shall. Four hours a day for school is confinement enough. I remember when it was six. Five hours are better than six and four will do better than five. Let us have playgrounds, industrial schools, swimming schools, cooking schools. Let our rivers and ponds be open for boating. Let there be some grass a child can step on, and see to it that we do not rob the child by rendering him unable to take food. It would be a pity, indeed, if we made our glorious common schools the means of physical degeneration. It must not be forgotten that the period of school life is the period of growth. It is now or never with the child. After years can not atone. What a shout goes up when the bell strikes for dismissing the school. Imagine the pupil of some old Grecian being glad that they could not go to the grove today, or of Socrates reminding Plato that he must keep his hands and feet in better position. Why not send our children out; one group to learn the geography of a park or river, one to find a wild flower, a butterfly or a geologic specimen; let him unconsciously find an appetite, and with it more food for brain. Sumner Ellis, a thoughtful writer, says of the age: "We are spent and why should we not be dull?" "Overwork leads to underfeeding." "Why not slacken into a greater speed?" This is to the point. The child who goes to school with uncaten breakfast, should be sent home for a supply of fuel. This plea is made for those conscientious pupils who deserve

well of the community, and who should not be enticed on by marks of no importance except to the over-sensitive. Says Montaigne, "The feast is in the palate." It belongs to us to emphasize this fact. Edward Everett was chosen as the orator at the dedication of the Gettysburg National Cemetery. He was the highest type, even the pinnacle of our classic education. No word would be admitted into his speech unless it could bear the test of good breeding. Every gesture even was fixed and irrevocable. Lincoln was to speak as the President of the United States. It is admitted that his friends were abashed at the prospect of the comparison. It is unnecessary for me to say anything more of the two men except that if asked who would be likely to deliver a classic oration, an oration that would be remembered and that would appear in the school books, I should have said Everett, and yet it was Lincoln. His words will be remembered as long as Gettysburg itself will be remembered. This shows that our ideas about what constitutes education may require modification. If this example is not enough, enough can be found. It surprises me that educators do not study the lives of forceful men, trace their lives back and see how they obtained their force, their education. Some philosopher has said that a man's education should be commenced a hundred years before he is born. It follows then that we should, in the education of a child, look forward a hundred years. We must have a care or nature will rebel and will give us no offspring to educate. Nature is patient and long-enduring, but she knows how to correct our errors by the decree that our race shall die out if we do not nourish our young.

SUBCUTANEOUS INJURIES OF SOFT PARTS.

BY JOHN EDDY LUCKEY, M.S., M.A., M.D.

VINTON, IOWA.

AWARDED THE J. W. FREER SECOND PRIZE, RUSH MEDICAL COLLEGE, 1897.

CONTUSIONS.

Contusions are surgical injuries—other than fractures or wounds proper—in which the skin is not broken. The producing force is usually blunt. Most wounds are more or less complicated by contusion. It may involve the skin alone, or any of the subcutaneous structures as muscles, nerves, viscus or bone. There is always present some degree of vascular rupture. A contusion may be defined as a hidden wound modified by the nature of its surrounding parts. Simple contusions are more apt to be found where there is a plentiful supply of fat or muscle interposed between the bony frame-work and the vulnerating force, upon the character of which the nature of the injury largely depends.

Symptomatology.—The pain which follows is not always proportionate to the injury. There is usually some degree of numbness, followed by marked aching or throbbing during the inflammatory stage, accompanied to a greater or less degree by loss of function. The inflammatory symptoms exhibit the usual features; however, owing to the protection of the wounds by the intact skin, sepsis is less liable to occur. Should the tissue be too much disorganized and the blood supply occluded, gangrene will follow. The writer recalls an injury of this nature which ultimately led to the loss of a boy's lower limb. In this case conservative measures were pursued, but the blood vessels

were crushed and gangrene followed, compelling double amputation. As a rule shock is present in proportion to the extent of the injury. However, very slight contusions of the breasts or of the testes, cause marked shock. The same may be said of the large joints. The discoloration of the tissues is familiar to all, and is well described by the popular expression, "black and blue." It is due to the extravasation of blood or blood tinged serum. The color under the mucous membrane is brighter than that under the skin. The distance from the surface, and the amount of blood in the effusion are modifying factors. At times the discoloration does not appear on the surface for some time, even for several days, owing to the depth at which the extravasation takes place. In these cases it appears as yellowish spots mixed with green and blue. After a time the blood corpuscles gradually disintegrate and become absorbed; the purplish hue fades successively into violet, olive-brown, green and yellow. In the majority of cases the abnormal color disappears in from ten days to two weeks, though in some cases it may persist for several months.

While the injury to the vascular system usually results in nothing more than ecchymosis, there are cases in which hematomas are formed. This confined blood may remain fluid for months or years, eventually becoming disintegrated, dark in color, and often mixed with inflammatory products. Absorption, however, is the rule, though in rare instances the clotted blood may become organized. If air enters a hematoma, rapid decomposition and suppuration follow.

Treatment.—The indications are¹: To limit the amount of extravasation; to subdue pain, shock and inflammation; in severe cases, to maintain vitality in the part; to promote absorption of effused blood, and to treat complications and sequelæ. Rest is important. Cold with gentle pressure and the limb in a position favorable to the return circulation will aid in limiting extravasation. Dry heat seems to be more effectual in superficial contusions. Heat and cold contract the caliber of the smaller vessels, and hence diminish congestion and extravasation. Moisture, with heat, softens and relaxes the tissues and so is contra-indicated. Although it gives temporary relief, it would by aiding effusion do harm. Heat or cold can be applied by rubber coil placed around the affected part and attached to some contrivance for regulating the temperature of the water if it be heated. To secure cold the tubing may be connected with the faucet of the water-works. Ice-bags and hot-water bags may be used. Subdue pain by opiates if necessary. Administer stimulants to overcome shock. Cold, blood-letting, leeches, saline cathartics and low diet aid in conquering inflammation. In cases where extreme disintegration of the tissues has taken place, cold is contra-indicated, as it tends to weaken parts already too much depressed. In such cases dry heat must be applied by the various methods that the conveniences at hand will suggest. The removal of the effused blood may be hastened by the application of heat or brief cold effusions, pressure and proper massage. Dr. Gross recommended the application (on a folded flannel) of a strong solution of hydrochlorate of ammonia to which has been added a little vinegar; the parts are then covered with oiled silk, and the application renewed six or eight times in twenty-four hours. Aneurysms, ruptured viscera, paralyses, neuralgias, hypertrophy, atrophy and other conditions may

¹ Reference Hand-book of Medical Science.

arise as complications or sequelæ, and must be treated accordingly.

SUBCUTANEOUS INJURIES OF MUSCLES.

Owing to their unprotected position, the muscles of the body are liable to injuries of varying severity. Contusions and sprains may result from external violence or from twisting and straining. The symptoms may be a mild form of myalgia, intensified by exertion and pressure with ecchymoses and swelling. In the more aggravated cases the pain may become intense, and the discoloration become marked. In cases complicated with rupture of the larger blood vessels hematoma may occur. When only the deeper muscles (as those of the thigh) are injured, it may take days before the infiltration of blood to the surface causes any discoloration. At times quite painful bruises of deep muscles may occur without any external signs. The injury of nerves in this connection intensifies the pain.

Shock may, and frequently does, complicate the injury. Loss of function, except in extreme cases, is temporary. Suppuration may follow.

Treatment.—Shock and pain should receive the same attention as in any other ailment. The very important remedy for the contusion itself is rest. This is secured by means of bandages and slings or splints, the choice depending upon the part affected. If rest can not be secured otherwise, put the patient in bed. Especially is rest demanded when the lumbo-dorsal region is the site of injury. Henry R. Wharton reports nine cases of contusions and sprains of the back, with special reference to early treatment of such injuries². Rest in bed was insisted on in these cases. Pain and discomfort were greatly diminished by strapping the back of the patient firmly with resin or rubber adhesive plaster two and one-half inches wide, and long enough to extend half around the body. These were applied so as to cover the back, one strap slightly overlapping the other from a point just below the junction of the last lumbar vertebra with the sacrum to the lower ribs. At the end of two or three days these were removed, but reapplied in cases where pain and tenderness persisted. This treatment seemed to have obviated the necessity of fomentations and stimulating lotions. Hemorrhage and serious effusion may be relieved by equable, elastic and firm compression. A simple flannel bandage cut on the bias is frequently sufficient for this purpose. Great comfort often follows the use of cold applications as ice-bags, or effusions of water, or evaporating lotions. The latter are most efficient in superficial contusions. Alcohol is the essential element in the tinctures so popular among the laity, arnica, witch-hazel, etc., and may be used with marked benefit. Cold applications are contra-indicated in cases where severe disorganization of the tissues has taken place. In such cases hot-water bags, warm flannels and other devices, may be resorted to for the purpose of supporting and stimulating the remaining vitality of the part. Later massage, with stimulating liniments, promotes the circulation, hastens absorption, promotes nutrition and re-establishes the normal function of the contused parts. In case of suppuration the part should be thoroughly incised and proper antiseptic treatment applied.

Rupture of muscle is not a common traumatism. Probably some of the cases reported as such are ruptures of the tendon, aponeurosis or sheath. This

lesion may be caused by a tremendous blow, by being run over by a vehicle, or by violent muscular efforts, as in running, jumping or trying to catch one's self when slipping. (Dr. Baldwin once ruptured his right plantaris while dancing.) Spontaneous rupture may follow even a slight voluntary movement when typhoid fever or other acute, grave pyrexia has caused a degeneration of the muscle fibers, rendering them peculiarly brittle. Rheumatoid arthritis ought to be mentioned in this connection. Sudden and violent muscular effort, followed by a period of prolonged inactivity is regarded as predisposing to the event. "The excessive action which takes place in convulsive disorders—as hysteria, epilepsy and tetanus—will occasionally cause solution of continuity in muscular tissue." The muscles of the abdomen, of the thigh and leg, of the back and of the arm may be affected, the frequency corresponding with the order in which they are named. Strong men are more liable to muscle rupture than are women. Parturition may rupture the abdominal muscles. Occupation may be a predisposing factor in rupture of certain muscles, for example, porters and hod-carriers are more liable to rupture of the cervico-dorsal muscles; cavalrymen, of the abdominal and thigh muscles.

Symptomatology.—The symptoms vary with the extent and location of the lesion. There is always pain, except in the spontaneous cases following disease. The pain is sudden, sharp, and stinging or cutting, like the lash of a whip—*coup de fouet*; it is a crackling sensation, and a snap, as of something breaking, may often be heard. Syncope follows in some cases. There is loss of motion. Swelling and ecchymoses are present. Separation of the disrupted ends causes a depression. Tearing of nerve fibers explains the sharp pain. These symptoms will usually afford a ready diagnosis; however, great care must be taken in deep-seated cases, in which diagnosis must be made by exclusion. Professor Pean cites a case where rupture of the anterior portion of the deltoid bore a resemblance to luxation of the shoulder joint. Dr. Mansell Moullin thinks rupture of a deep-seated, perhaps degenerated vein, constitutes the lesion of *coup de fouet*, and not separation of muscular or tendinous fibers. He refers to a case in which this lesion occurred twice in the same leg, at different spots, during the same month. In both instances, under proper treatment, there was rapid recovery, which to him indicated lesion of a blood vessel. It is doubtful whether rupture of a vein alone would cause such sudden, excessive pain and loss of function. Such a lesion of a vein would cause greater hematoma and swelling, and more marked ecchymosis. Sédillot analyzed twenty-one cases and found all affected at the line of insertion between muscle and tendon, while there were also eight lesions in the body of the muscle. Nélaton found the situation of the lesion dependent upon the form and structure of the muscle. Those with long fibers and short tendons ruptured from injury to the fleshy parts. Those with short fibers and long tendons ruptured at the junction of tendon and muscle. In the latter, the rupture is more apt to be complete. Hematoma is almost constant. The extravasation is usually absorbed and repair takes place. Suppuration is rare in the previously healthy. Complications are usually not severe. Thrombosis may take place. Contracture and shortening may follow.

Treatment.—Relaxation and rest, with ruptured

² Med. and Surg. Reporter, Vol. lxx.

parts in approximation and under gentle pressure. When the muscle is perfectly healthy, the parts may be sutured. It will take from four to eight weeks to accomplish good results, and even then feebleness may linger. Varicosity may be avoided by use of the roller bandage. Contracture and shortening may be compensated by Anderson's method of lengthening tendon.

Hernia of muscle may take place, in consequence of the imperfect healing of a wound. It may be due to rupture of the muscle sheath following some severe exertion or unaccustomed movement. This condition may be recognized by the tumor, which is soft during relaxation of the muscle, and hard during its contraction. This tumor may persist for an indefinite period. "In recent cases, rest and methodical pressure will generally effect a cure. When the hernia has long existed, the edges of the opening should be freshened and united by stitches." Inconvenience may be so slight as not to justify any surgical interference.

SUBCUTANEOUS INJURY OF TENDONS.

Rupture of tendons may be the result of sudden exertion. It may be complete or partial, usually the former. Exertion that is not exaggerated may cause rupture in tendons of defective structure, as in Dr. Becker's case cited below.

Symptomatology.—Rupture of a tendon frequently causes a snapping sound. There is a sensation of something giving away. Pain is not so pronounced as in similar lesions of muscles. Loss of motion follows the lesion. There is a gap at the seat of injury, which is increased on contraction of its muscle. This depression may be felt and frequently seen. A rupture of the tendon of the quadriceps extensor causes severe swelling of the knee joint, due to effusion into the joint.

Dr. Becker³ reports a case of subcutaneous rupture of the tendon of the quadriceps extensor, in a laborer who caught himself in slipping while carrying a load on his back. On making the incision for the sutures, fully one-half pint of blood escaped. In this tendon three cartilages had grown, from one-fourth to one-half inch in diameter. As they weakened the tendon, these were excised. The leg was antiseptically treated, and a good recovery made, though the shortening of the tendon caused the leg to remain bent at an angle of 90 degrees.

Treatment.—Approximation of the separated ends, by holding the parts in position by splints, bandages or other mechanical devices, until reunion takes place, which will usually occur in five to ten weeks. The better method is by suture, especially when it is difficult to control the contraction of the muscle. Operation is especially indicated in the leg, except in extreme age or other clear contra-indications. Aseptic surgery advises operation, even in old cases of rupture, where extensive dissection is required to find the widely separated and buried ends.

Displacement of tendons occurs sometimes, in injuries consequent upon sudden muscular action or great violence. The peroneal tendons are the most frequently affected. After pressing the tendon back into position, the parts should be immobilized and retention dressing worn until repair of the torn sheath or lateral ligaments takes place, if this can be secured. It may be necessary to resort to sutures. Dr. White has reported a case of dislocation of the tendon of the long head of the biceps, flexor cubiti.

SUBCUTANEOUS INJURIES OF ARTERIES.

The arteries may suffer from contusions and strains. The walls of the artery may be ruptured so as to admit hemorrhage into the sheath, and this blood may produce such pressure as to cause partial or total occlusion of the vessel. Rupture, to a greater or less extent, of the internal and middle coats, is the most common result of contusing and stretching. The retraction of these coats, the outer coat remaining intact, produces obstruction. In cases where the vessel is so surrounded as to confine the extravasated blood in a cavity, hematoma may follow. The healthy artery recurves in a valvular fashion, while the diseased artery breaks up irregularly. Aneurysms, in the young and otherwise perfectly healthy subject,⁴ sometimes follow severe strains. Fractures of the bones are a fruitful source of injury to the blood vessels. In some cases damage to the vessel walls may be so serious as to preclude return of function. In other cases of simple organic injury, obstruction may be but temporary. Where the artery remains intact, pulsation soon returns, though pressure overcomes it for a time. The following case illustrates the condition mentioned above, in which the internal and middle coats are ruptured:

A youth of 18 years entered Middlesex Hospital Sept. 13, 1894, complaining of injury to the upper part of his right thigh. Shortly before his admission he had been crushed between the sliding table of a press and the wall. He had walked without aid to the hospital.

Slight bruises were discovered on the anterior aspect of the upper part of the thigh, about an inch below the fold of the groin. No swelling; slight pain and tenderness; no discoloration beyond seat of bruises. The entire right limb was colder than the left. No pulsation in the common or superficial femoral arteries or in the posterior tibial and dorsalis pedis arteries. Pain ceased in two days. Signs of bruises slowly vanished. Could move limb freely two days after accident. Thirteen days after accident a slight pulsation in the dorsalis pedis artery was noted, but none in the posterior tibial or femoral. Three days later there was a distinct pulse in the dorsalis pedis. October 3, pulsation in posterior tibial. The femoral artery remained unchanged. Patient left the hospital October 4.⁵

Since there was no swelling in the above case, there could not have been rupture of the external coat of the femoral artery. The loss of pulsation in the common femoral, posterior tibial and dorsalis pedis arteries of the right limb, with coldness of the entire limb, justified the diagnosis which was made, "rupture of the inner and middle coats of the right common femoral artery." Collateral circulation, in this case, probably took place through the external circumflex and terminal branches of the profunda artery.

Symptomatology.—When but partially occluded, there will be slight pulsation on the distal side of the lesion; total occlusion would cause entire loss of pulsation. The parts will be more or less swollen, depending upon the amount of general contusion present. In cases where the great artery supplying a limb is occluded—as the brachial or the common femoral, as noted in the case above—the limb will be cold. There may be numbness. Pain will vary with the extent of nerve injury.

Treatment.—Wrap the part in cotton; secure rest for the part—splints may be adjusted to the limbs. Treat shock, if present, as in all cases—warmth, stimulation and by staying hemorrhage. Constitutional treatment may be demanded, depending on the general condition of the patient. Treat contusions as outlined above.

SUBCUTANEOUS INJURY OF NERVES.

The nerves, like all the more vital organs of the body, are anatomically well protected. Those of the upper extremities are the more exposed, and for this reason, injuries are more common to nerves of these parts.

Contusions and compression are the most common of the injuries, though at times dislocations of the nerves are also met with. Direct blows may affect the nerves, causing severe pain and, at times, shock. Every one is well acquainted with the sensations due to striking the "crazy bone." These are due to concussion of the ulnar nerve as it crosses the bend of the elbow. The sporting fraternity are well aware of the effectiveness of a blow at the base of the neck causing contusion of the brachial plexus. Dislocation or fracture of various bones may give rise to serious contusion of the neighboring nerves, laceration being especially liable to follow fracture. In one of the clinics of the past year Professor Senn (Rush Medical College) presented a boy with fracture of the bones of the forearm, with faulty union and involvement of the nerves, causing loss of sensation in the hand and forearm. Fracture of the humerus frequently causes laceration of the musculo-spiral nerve, and the brachial plexus may be implicated in fracture of the clavicle, while the sciatic nerve may suffer from fracture through the sciatic notch. Compression of a nerve may cause partial or complete loss of its function. This compression may be continuous or repeated at very short intervals. It may be due to excessive growth of callus in repair of fracture; to tumors, especially thoracic aneurysms; to lying in cramped positions, as with the arms under the head; to exostoses; to contraction of scar tissue; to the use of crutches; to the use of forceps during labor; to prolonged compression of the pelvic nerves during protracted labor. Various mechanical injuries may tear or compress the nerves, causing hemorrhage into the nerve structure and affecting the myelin. Very severe subcutaneous injuries may even cause destruction of the nerve.

Symptomatology.—In contusion, there is a tingling sensation, as of pins sticking. In severe cases, loss of function may follow immediately. Occasionally a severe neuritis may develop, with pain in the distribution of the nerve. Palsy may be present, and trophic alterations may be among later symptoms.

Treatment.—Remove the cause when it is possible. Absolute rest is essential and morphin may be used to allay the pain. Arsenic is sometimes useful and galvanism may be beneficial.

Dislocation of nerves is rare. A blow may cause dislocation of the ulnar from its groove behind the epicondyle. Poncet⁶ records an instance in which the dislocation was due to muscular effort exerted in throwing a snowball. Cases have been observed with no history of traumatism.⁷ Holden⁸ reports dislocation of both ulnar nerves while the patient was holding the steering wheel of a vessel during a storm. The patient felt something slip in both elbows, and a tingling pain in the distribution of both ulnar nerves. The nerves returned to their normal position on exerting slight pressure on the inner side of the elbows.

Treatment would be the same as in displacement of the tendons. Complications must be treated according to their nature.

INJURIES OF THE CHEST AND ITS VISCERA.

Contusions of the chest are very common but, owing to the extreme elasticity of the chest walls, they are seldom serious. Mild contusions give rise simply to bruises and ecchymosis. Abscess seldom follows such injuries. Fracture of the ribs is a frequent result.

Symptomatology.—The symptoms are pain, soreness, limited motion in breathing and abdominal respiration in injuries of considerable extent.

Treatment.—As in all contusions, the securing of rest is essential. This may be accomplished by compressing the chest wall so as to limit motion. The application of adhesive strips as directed under contusions and strains of muscles, would serve excellently in these cases. Other appropriate treatment for contusions and sprains should be adapted to the demands of individual cases.

Contusions involving the thoracic viscera may be of the most complicated and serious character. Rupture of the lungs, the heart, the pericardium, and of the blood vessels, may occur without external evidence of injury. "Commotio thoracica" is analogous to contusion of the brain—no postmortem evidence of mortal lesion ever having been discovered. Bruises of the lungs may result in varying degrees of injury. There may be simply rupture of the capillaries not involving the pulmonary tissue itself; there may be small ruptures of the lung tissue extending into the alveoli and bronchioles and including the surrounding vessels, which form depots of blood here and there in the neighboring tissues. In these cases recovery usually follows, provided there is no inflammation; but where the rupture becomes extensive, including the bronchi and larger vessels, death in many cases results very soon. Hemothorax, pneumothorax and emphysema are present after ruptures of the lung, in degrees varying with the amount of damage done. In making a diagnosis the signs and symptoms of these conditions must be kept in mind. Complications are apt to arise in the shape of bronchitis or broncho-pneumonia, traumatic pneumonia, pleurisy or gangrene. More or less impairment invariably accompanies recovery.

Treatment must be directed toward the relief of the conditions as exhibited in the individual cases.

Pneumocoele, or hernia of the lung, is very rarely met with. In the civil war seven cases of pneumocoele were recorded, and of these six were primary. While a few cases of the lungs escaping at the root of the neck, simulating in position and outline aneurysm of the great vessels, are reported, the greater number are found in the lower portion of the chest. When in the neck they may transmit such impulse and murmurs as to seriously embarrass diagnosis.⁹ Pneumocoele is usually the result of some penetrating wound, as a stab or gunshot wound; however, the unique case reported by E. Clifford Beale in the *Lancet*, Jan. 28, 1882, justifies mention of the subject under subcutaneous injuries. This was the case of a young carter, who was admitted to the hospital in a state of extreme shock, Aug. 11, 1881, having been seriously injured by his own cart, from which he had fallen. The patient subsequently dying, part of the lower lobe of the right lung was found to have been forced into the abdominal cavity. The presence of the liver on the same side would oppose such protrusion except in case of unnatural conditions, such as a congenital fis-

sure of the diaphragm. The writer has been unable to discover any directions for treatment, except in *penetrating* wounds resulting in protrusion of the lung. In such cases the parts should be cleansed and restored to normal position, or if it is adherent, ligature or excision is recommended.¹⁰ In cases of subcutaneous lung hernia where the diagnosis is clear and the symptoms aggravated, the surgeon might be justified in cutting down to the parts, reducing the hernia or excising it as the conditions seemed to require.

Rupture of the diaphragm, in a patient whose condition is favorable, may be repaired by abdominal incision and restorative procedure. The operation requires skill and rapidity, and is of so difficult a nature as to demand the most careful attention of the best operators.

The heart may suffer from contusion, just as the other viscera. Carditis, endocarditis and pericarditis may be caused by contusion. These affections will be recognized by their characteristic signs and symptoms.

Treatment of these cases must include both constitutional and local measures. Absolute rest in the recumbent position is imperative. Opium may be used to allay pain, and for its sedative effect on the circulation. Collapse calls for artificial warmth and, to a certain extent, is a favorable condition, since it tends to check hemorrhage and inflammation. Violent reaction, following in some cases, necessitates the administration of cardiac sedatives. When inflammation of the myocardium, pericardium or endocardium results, the treatment is the same as for like affections from idiopathic causes.

Rupture of the heart.—The belief is firmly established in the popular mind that the heart is the most vital structure of the whole organism, and that the least interference with its function by external forces means immediate death. Records of wounds of the heart are not numerous, but out of twenty-nine collected cases of injury to this organ, only two were fatal within forty-eight hours.¹¹ This contradicts the popular view on the subject. The heart has suffered severe injury and such recovery been made as to enable the patient to live for years afterward.¹² Since this is true of incised wounds, it is true also of ruptures. In this connection the case below, reported by Prof. L. Hektoen,¹³ is of rare interest:

The patient was a young baggage master with good family history, good habits and extraordinarily good health previous to February, 1891. At that time, while carrying a heavy trunk, on a rapidly moving train, he was thrown on his back by the train striking a curve. As he fell he exerted his entire strength to save himself. He felt a stabbing pain near the heart and heard a snapping sound. Three or four days later, a rumbling sound from the heart, occurring synchronously with its beats, became sufficiently distinct to be heard across a room of ordinary size. Peripheral pulsation was well marked. Later the sound disappeared, but there was shortness of breath, pain in the chest and palpitation of the heart, increasing to the time of his death, with additional symptoms of ascites and anasarca two weeks before death, which occurred somewhat suddenly in March, 1892. Physical examination Jan. 31, 1892, gave labored respiration, quick pulse, diffuse and lifting pulse in epigastrium and sixth or seventh space in left anterior axillary line, also in neck and crural regions. Area of cardiac dulness was increased. Rough diastolic murmur over base of heart, and diffuse systolic murmur at apex. A distinct murmur was heard over carotid, subclavian, brachial and femoral vessels.

Diagnosis.—History, symptoms and physical findings gave

diagnosis of rupture of healthy valve, probably one of the aortic, causing an insufficiency which became permanent and led to hypertrophy and dilatation of left ventricle.

Fig. 1.—Heart with extensive ruptures at aortic orifice. (From Dr. Hektoen's article, by permission.) A, ridges of cicatricial tissue; B, cicatrix, from tearing of right posterior segment along attached margin; C, orifices of coronary vessels; D, anterior segment, cut across.

Postmortem.—Heart, weight 20 ozs.; apex formed by both ventricles, coronary veins on both surfaces distended; both sides of heart filled with fluid blood: left ventricle increased in depth and in thickness of its walls, right ventricle increased in depth, but diminished in thickness of its wall; papillary muscles compressed; semilunar valves incompetent to water test; orifices of aortic, mitral and tricuspid valves increased in size; valve leaflets uniformly thickened but showing no degeneration in structure; orifices of coronary arteries 1 cm. above free margins of aortic valves, instead of immediately behind; the left third of the convex attached margin of the right posterior segment of the aortic valve was torn loose from the vessel wall, its site of attachment showing a dense linear cicatrix, while the segment itself hung free (Fig. 1). Three

Fig. 2.—Saccular aneurysmal dilatations in upper margin of right auricular appendix. (From Dr. Hektoen's article, by permission.)

ridges, as of cicatricial tissue, were upon the wall of the aorta, at points of usual joint attachment of valves to aortic wall. These ridges varied in length from one half in. (1.5 cm.) to one third in. (1 cm.), and showed characteristics of recent scar tissue. The valves were reattached lower down. Two small aneurysmal dilatations of the right auricular appendix showed walls composed only of epicardium and endocardium (Fig. 2).

Conclusions:—The principal lesion was at the aortic orifice, insufficiency here causing, secondarily, hypertrophy of the whole heart. This insufficiency at once occurred, when the right posterior segment of the aortic valve was torn, and continued, in consequence of the failure of this leaflet to reunite.

The muscular strain attendant upon the accident caused also the tearing loose of the three points of joint valvular attachments, leaving scar tissue on the wall, while the valves united again at a lower site (Fig. 1). This lower attachment accounts for the peculiar situation of the coronary arteries. The aneurysms of the right auricular appendix would result from the increased intra-auricular pressure.

(To be continued.)

"DEFICIENT EXCRETION FROM KIDNEYS NOT ORGANICALLY DISEASED AND SOME OF THE DISEASES PECULIAR TO WOMEN," AND DISEASES OF THE SKIN.

Read before the Medical Society of the State of New York, January 7, 1897.

BY L. DUNCAN BULKLEY, A.M., M.D.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL ETC.
NEW YORK.

One year ago Dr. James H. Etheridge of Chicago, by invitation, made an address before this Society, the title of which was the first portion of that above given.¹ As there was no discussion except some remarks by the present writer it seemed best to present the matter again, with the author's full consent, in hopes that the important subject might receive further consideration from the members present, and that it might thus become doubly impressed on those likely to meet the cases referred to.

While the present writer disclaims all special knowledge in regard to diseases peculiar to women, he feels particularly interested in the subject which Dr. Etheridge so ably presented, for several reasons. Incidentally he has met many female patients, coming under treatment for various diseases of the skin, who were known to have also various uterine disorders of distressing character. Many of these patients had previously undergone prolonged and varied gynecologic treatment, often with unsatisfactory results. These uterine disorders he has seen improved and often quite recovered from, under lines of treatment directed for their skin difficulty, which quite coincided with those laid down by Dr. Etheridge, and without gynecologic treatment. He therefore begs to present the subject again, as briefly and clearly as possible, urging the profession to recognize the principles and employ the methods laid down by the distinguished author of the paper alluded to.

Dr. Etheridge has kindly given permission to use in the freest manner possible the material presented by him, which will be done as far as necessary to make the matter clear and forceful.

"Toxic materials always reside within the human body. They constitute the waste products of living beings. From birth to death they battle for supremacy. So long as they are plentifully excreted, death is postponed. The skin, the pulmonary mucous membrane, the bowel and the kidney constitute the avenues of escape for all toxic materials from our bodies. If one of these emunctories be crippled the

initiation of death is manifest. . . . The physician who busies himself with solving the problem of the initial departure from the proper performance of excretion enters a new field of labor. It is the most interesting one he can invade today. . . . Herein he deals with the beginning of disease." Such are the strong words with which Dr. Etheridge introduces his interesting and important study.

Prominent among the systemic derangements which tend to the impurification of the blood current, and the retention in the system of the waste products of animal life, undoubtedly stand imperfect kidney excretion; the elements composing the urine are known to be poisonous both to the individual forming them, and also to animals, when artificially introduced. Extirpation of both kidneys is very quickly followed by death; the gradual retention of these normally excreted poisons, by means of imperfect elimination from the kidneys, leads, as many have shown, to various forms of disorder and disease in many organs of the body.

Dr. Etheridge has rendered an inestimable service to the profession, and to suffering females, in earnestly calling attention to the fact, which I can confirm most positively, that this insufficient kidney secretion plays a very important part in the production and continuance of many of the diseases peculiar to women. The study of the initiative cause of these diseases merits the most serious consideration of the profession.

How far the errors observed in the excretion from the kidneys pertains to the action of those organs alone, does not belong to our present discussion; nor how far the remedies used have for their action solely their influence on the kidneys. Undoubtedly the liver plays a very important share, as also the digestive organs, in rendering the ultimate process of removal of effete products imperfect. Suffice for the present that we discover in the kidney excretion the evidences of the imperfect removal of the waste and poisonous substances, and by means of the improved excretion from the kidneys we find the proof of their proper removal and consequent good health.

Recognizing that the proportion of the solids in the normal urine bears a certain ratio to a normal body weight, below a certain percentage of which they can not fall without indicating "renal insufficiency," Dr. Etheridge has given a table, prepared by an expert physiologist, which is here reproduced:

TABLE 1. Relation of body weight of healthy human beings to total daily excretion of urinary solids:

Weight.	Total urinary solids.
40 pounds.	392 grains.
50 "	479 "
60 "	563 "
70 "	639 "
80 "	716 "
90 "	789 "
100 "	854 "
110 "	916 "
120 "	974 "
130 "	1028 "
140 "	1078 "
150 "	1150 "
160 "	1198 "
170 "	1237 "
180 "	1260 "
190 "	1300 "
200 "	1330 "

As this table was constructed for healthy human beings, and takes into account exercise, Dr. Etheridge does not think that practically quite these amounts can be expected in women who come for treatment. It is to be remembered also that women always excrete

¹ Transactions of the Medical Society of the State of New York, 1896.

less than men, perhaps one-tenth less. He would, therefore, from experience fix the limit at 500 grains for a woman weighing 90 pounds, and 1,100 grains for one weighing 180 pounds; from which data a scale can easily be constructed, as follows, for practical daily work:

TABLE 2.—Relation of body weight of women of average health to total daily excretion of urinary solids:

Weight, pounds	Total urinary solids, grains.
90	500
95	535
100	570
105	605
110	640
115	675
120	710
125	745
130	780
135	815
140	850
145	885
150	920
155	955
160	990
165	1025
170	1060
180	1100

This table is at the rate of about thirty-five grains additional for each five pounds of body weight, or seven grains to the pound, which is near enough for ordinary daily work. For greater accuracy there should be still some deduction for age; thus, between 40 and 50 years, deduct 10 per cent., between 50 and 60 deduct 20 per cent., and between 60 and 70 deduct 30 per cent. from the amounts above given.

It is not a very difficult matter to carry out the plan of learning the total daily excretion of solids, if it be rightly arranged; it is especially easy in regard to women, as they are more apt to be at home and willing to attend to such matters. I have long had it done, daily in many instances, and in others at stated intervals. An ordinary two-quart mineral-water bottle is used, with a strip of paper pasted on the side for the scale. This is graduated by filling the bottle from a two-ounce measure and marking off each two ounces; the intervening ounce can be divided by the eye. Many druggists keep large bottles graduated for this purpose. A glass funnel is placed in the mouth of the bottle, by means of which all the urine can be poured into it as passed. The index is read off, the amount recorded and the bottle emptied at a fixed hour every day and a sample of the whole is sent to the office, with the statement of the total amount passed. From the specific gravity of the sample the total amount of solids passed in the day is easily estimated by Haines' modification of Haeser's method, as given by Dr. Etheridge; which is as follows: *Multiply the last two figures of the specific gravity of the urine by the number of ounces voided in twenty-four hours and add 10 per cent. to the product.* Thus, if the amount passed in twenty-four hours was 36 ounces and the specific gravity 1021, it would be $36 \times 21 = 756 + 10 \text{ per cent.} = 831$, the number of grains of solids in the whole amount. Compared with the table it can be readily estimated if this is above or below the normal amount of the body weight of the patient.

It will be noticed that this estimate is for the total solids of the urine and not for the urea alone; the tests for the latter are slow and laborious and while often extremely valuable are really not necessary here; for, under normal conditions the urea represents

nearly one-half of the solid constituents of the urine, and so would be expected to vary with the total solids. It is to be remembered that our study is in regard to kidneys not organically diseased, and at present no reference is made to albumin in the urine or to sugar.

But, further, the toxicity of the urine does not depend upon the urea alone. Etheridge states that "the coloring matter and other organic substances removed by charcoal filtration contribute at least one-half of the toxic power of the urine," and he attributes a considerable portion to the urinary salts of potassa.

It will be noticed, however, that very little has been said in regard to the actual quantity of the urine passed, representing the amount of water in it or the solubility of its constituents, a point hardly alluded to by the writer of the previous paper. The urinary water may vary so greatly from day to day, according to the amount of fluid drank and the activity of the secretion of the skin and respiratory organs, that it is in some ways of less importance than the actual solids of the urine, which represent the removal of the waste products of metabolism from the body. But, on the other hand, it is often immensely important and should always be known and appreciated. For even if the total amount of solids voided may be up to normal, there is still insufficiency of kidney action and consequent ill health if the proportion of water be not also about normal. A smaller amount of water, with higher specific gravity, and consequently containing a normal daily amount of urinary solids, does not conduce to the good health which a normal amount of urine with a lower gravity would indicate. Clinically this matter is often of the very greatest importance, and I could illustrate it by dozens of cases, did time and space permit.

Dr. Etheridge gives some very interesting cases illustrating the ill effects of renal inadequacy and their relief upon the employment of appropriate diuretic treatment, which I will very briefly quote before adding my own clinical statements and comments.

Case 1.—Mrs. C., multipara, had general metritis with deep double laceration of the cervix, with an obstinate bronchitis and profuse secretion; the severity of the cough increased the pelvic suffering and vesical irritability, also the profuse leucorrhea. Each winter she had been an invalid, submitting to very much gynecologic treatment, and had sought relief in warmer climates, where she was better, as also in summer; but with advent of cold weather the bronchitis returned, aggravating all her other troubles. Finally it was found that she was passing only 298 grains of urinary solids, when 850 grains was her normal amount. Under stimulating diuretics, tonics and a laxative, the urinary solids were increased, in thirty days, to 950 grains, the cough had disappeared, though in mid-winter, and she was shortly in better condition than for many years.

Case 2.—Miss G., aged 23, had menstruated only five times in the previous year; she had backaches and headaches, circumpelvic pains, increased by exercise, an albuminous leucorrhea and great nervousness. The ascending colon was loaded with feces. She should have voided 850 grains of urinary solids daily, but was passing only 485. Under treatment of laxatives and diuretics the urinary solids were increased to over 1300 grains for a number of days, and regular menstruation returned. When, from neglect, there was again insufficiency of the solids in the urine, the amenorrhea returned, and a recurrence to diuretics again made her monthly sickness appear regularly.

Case 3.—Mrs. B., aged 36, the mother of three children and the victim of many abortions, complained of pelvic weight, general rachialgia, tender spine, pleurodynia in left chest, excessive nervousness and moderate metrorrhagia; she had a moderate metritis. She weighed 154 pounds and should have passed 900 grains of urinary solids daily, but was voiding only 480 grains. Her urinary solids were kept above 1000 grains daily for many weeks, and with local treatment and tonics she was cured in four months.

My own experience in regard to the value of diuretic treatment in many disorders peculiar to women dates back a good many years, and has come to me slowly though very convincingly. But I have always hesitated about reporting on the subject, because of my want of acquaintance with the actual condition of the pelvic organs, except from a report made by those who had previously seen the case or cases, aided by statements of the patient. But as I have gone on year after year, seeing and knowing of the vast improvement which occurred in my patients in regard to symptoms pointing to the pelvic organs of which they had complained, I have become more and more confident as to prospective results, when patients complained of uterine or other pelvic derangements.

When, therefore, Dr. Etheridge spoke with such positiveness, I was pleased indeed to find my own experience verified by so distinguished an authority, and I felt justified in adding my testimony to the same facts, observed from quite a different portion of the medical field; for it need hardly be added that my cases came to me for various diseases of the skin, and not for uterine or female troubles.

The first case, which impressed me perhaps most forcibly of all, occurred at least fifteen years ago; the name of the patient has gone from me so that I can not look up the notes of the case, but the details are yet very vivid to my mind, for many reasons.

My patient was a girl of about 23, with one of the worst cases of indurated acne that I had seen, the cheeks and chin being dreadfully disfigured. She gave the history of very great uterine trouble, for which she had received an infinity of treatment for a number of years. She had profuse menorrhagia with very great pain. Her condition had become so bad that an elevator had been put in her house for her use, as she never could go up stairs. She drove to my office and, as it was on the second floor of a basement house, I saw her the first few times in the reception room on the ground floor.

For her acne I gave her first alkaline diuretics and laxatives, tonics, etc., with a regulated diet, and she responded well to treatment. I remember well my surprise when one day she walked up stairs to my office. I shortly persuaded her to take a little exercise, walking a block and gradually more, and, to be brief, by the time the treatment for the acne was completed she walked a mile to my house and had abandoned her elevator at home. She had had no gynecologic treatment in the meantime, and I do not think that I knew what condition existed in the pelvic organs. Simply in treating the condition I found on the face the general results followed, and this treatment was very decidedly in the line of a relief to insufficient kidney and bowel action.

It is hardly necessary to occupy time in relating individual cases, and indeed it is difficult to make selections from the notes of several dozen cases now before me, there are so many which exhibit gains in the directions mentioned to a striking degree. It is really now of daily occurrence for me to see those who have suffered from many of the diseased conditions peculiar to women, become freed from them under treatment directed largely along the lines advocated by Dr. Etheridge, and given mainly on account of skin diseases for which they sought relief. And I may say that almost without exception such cases have exhibited insufficient kidney action, many of them,

of course, being also complicated with constipation and primary or secondary indigestion.

In this way I have seen many patients with amenorrhea in varying degrees, in whom the menses have been thus established in a regular manner; but as in Dr. Etheridge's case, their trouble will often return when the treatment has been neglected for some time, and from one cause or another the insufficient action of the kidneys returns. We all know of many instances where the menstrual flow has been suddenly checked by chilling of the feet, and it is just the same accident which so often deranges kidney action. Irregularities of the menses, as to the interval and their duration, have also constantly been observed by me to disappear as the eliminative treatment necessary for the skin disease has gotten under full action. Excessive flowing has also been met with from time to time, which has been regulated by the same line of treatment.

But it is in dysmenorrhea that the largest number of most interesting cases are found, and of these I could give many very striking examples. It is not at all uncommon for me to learn from a patient that since she had been under treatment the monthly flow had become more regular and natural than for years previously. Many who have suffered so severely that even opiates were required with each monthly sickness, in order to make life endurable, have, when under full treatment, absolutely lost all pain and become even unconscious as to when the menstrual epoch begins. And it has occasionally happened that a mother has brought a second daughter to me, not at all for the treatment of any skin disease, but solely for the relief of menstrual difficulties, because another daughter had found such benefit while under treatment for the skin.

My experience in a very considerable number of cases has also led me to the belief that many of the ills and discomforts complained of at the period of the menopause, and usually more or less accredited to this condition, as though dependent upon it, are in reality due to faulty elimination, principally by the kidneys. I could cite many many instances where attention to this element has resulted in the disappearance of the unpleasant symptoms in very brief time, while a neglect of the same would be followed by their recurrence, only to again disappear under exactly proper treatment.

I am quite aware that some of the statements I have made may seem exaggerated, and I may seem unwarranted in speaking thus positively in regard to matters outside of my chosen specialty. I can only assure you that I am speaking of what I have observed and know; for surely even the gynecologist can not know of the sufferings of patients except from their own statements; and I can verify the facts by many physicians who have seen cases with me. I may also say that in the local societies and to friends I have mentioned these ideas, and others have seen like good results in patients where this plan of treatment has been put in thorough practice.

It will be understood that in the cases referred to there has been no local or gynecologic treatment employed at the time, as I never in any way attempt such; nor have I generally known what, if any, local disorder or displacement existed, as I never make examinations in such cases, but send patients to gynecologists when special treatment is required.

I do not, however, wish to be misunderstood in regard to the matters of which I have spoken. I by no means claim that care in regard to deficient urinary secretion

will cure all the ills which woman is heir to. I most fully appreciate the need of the gynecologist, and recognize in the highest degree the splendid work which has been accomplished by them in the relief of suffering women. But from experience I know that many cases of uterine disorders can be relieved and indeed cured by full and adequate general medical treatment, including attention to and rectification of a faulty urinary secretion, which had too often been previously neglected. I can not do better than to close with a quotation of the final part of Dr. Etheridge's excellent paper.

"No intimation is here given that this is the most important factor in diseases of women. To set up such a claim would be most absurd. The aim of this article is solely to call attention to one line of treatment that has been all but universally neglected heretofore, and to invite observation and original investigations.

"There is the gravest reason for thinking that a very close relation, even that of cause and effect, exists between renal insufficiency and pelvic disorders. The developmental phase of the renal and generative organs constitutes that reason. Embryologically these two sets of important organs arise from the same source. The mesoblast in the ovum gives rise to the muscles, bones, circulatory and lymphatic systems, the urinary and generative organs. From this fact it becomes an easy matter to infer that derangements in one set of these organs can produce, in a reflex way, if you please, or at least are very frequently associated with, derangements of the other.

"Since observation shows the numerous cases of coexistence between renal insufficiency and neuralgias, mucous membrane disorders and serous membrane inflammations, one can not question the possibility of this insufficiency producing or permitting amenorrheas, dysmenorrheas, leucorrhoeas and attacks of pelvic peritonitis. It is strongly emphasized that the position is not assumed that all cases of these disorders are produced by renal insufficiency, but from the fact that many of them are relieved by including in the treatment remedies that increase the urinary solids, the conclusion can not be resisted that cause and effect actually exist between many of them and the deficiency of urinary ingredients."

4 East 37th Street.

IMPLANTATION OF A GLASS BALL FOR THE SUPPORT OF AN ARTIFICIAL EYE AND MULES' OPERATION FOR THE SUBSTITUTION OF ENUCLEATION OF AN EYEBALL.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY L. WEBSTER FOX, A.M., M.D.

PHILADELPHIA, PA.

The satisfactory results attending evisceration for the better support of an artificial eye have led me to implant a glass or silver ball in those cases where the eyeball had been enucleated at an earlier period.

After an enucleation, and the artificial eye is adjusted, we have the objectionable enophthalmus and a fixed eyeball stare. Owing to the sinking of the artificial eye the secretions are retained in the cul-de-sac and in a short time we have the muco-purulent

discharge, which adhere to the margin of the lids and also crust the anterior portion of the artificial eye, rendering the wearing of it most objectionable.

It was to overcome these objections that Mr. Adams Frost of London, in 1886, practiced the insertion of a glass ball immediately after enucleation of an eyeball. His method was as follows: After incising the conjunctiva all around the cornea, each rectus muscle was raised on a hook, seized with forceps, severed from its attachments and secured by a ligature; the eyeball was then removed and the glass ball introduced. The tendons were next united across the ball by means of the sutures previously passed through them, and finally the conjunctiva was brought together. Out of seven cases, Mr. Frost could only claim one successful operation.

Mr. Lang of Moorfields improved on Frost's method by placing the artificial globe in Tenon's capsule, which was sewed up and the conjunctiva then sewed over this. I have followed this method where the eyeball was atrophied and in several cases of simple enucleation, very successfully.

It is where the eyeball has been removed and when shrinking of the tissues has taken place that the implanted globe proves its value.

My first three operations were performed in 1895, and during the year 1896 I performed fourteen operations. In five of these cases the stitches broke and the glass ball came out. After two months I performed the second operation in the same socket. In two of these cases I operated the third time before the glass ball remained. I have found that it is useless to try restitching where the thread has cut its way out. If the wound does not heal by first intention the glass ball will be expelled by tissue contraction in spite of all protective measures.

My method is as follows: An incision is made through the conjunctiva and tissues of the orbit in the horizontal direction, corresponding scant to the diameter of the glass ball to be inserted; for instance, if the glass ball is one centimeter in diameter, the cut would be two millimeters less. The upper lip of the conjunctiva is raised, and with a sharp-pointed, curved scissors the conjunctiva and such connective tissue which lies close to it is dissected off in all directions around the incision, making a pouch into which the glass ball will fit. On account of the vascularity of the parts considerable bleeding follows this dissection, but it is easily controlled by pressure. After the bleeding stops the glass ball is inserted into the cul-de-sac with the injector. The edges of the conjunctiva are brought together by five or six stitches. Experience has taught me that it is well to keep the pressure bandage over the orbit from forty-eight to seventy-two hours. With the aseptic measures adopted in carrying out the details of the operation there will be little or no reaction. In the very few cases (two) where there was more or less pain, a few hypodermics of morphia controlled this. As regards the permanent stability of the implanted ball, time alone will tell, but of the fourteen operations performed in 1896, two balls came out ten months after the operation. There was a gradual thinning of the tissues over the globe, which was probably caused by posterior contraction of the orbital tissues, or possibly the artificial eye pressed so pronouncedly against the ball as to impede circulation, causing considerable attenuation and eventually rupturing of the conjunctiva, allowing the glass ball to escape.

MULES' OPERATION (EVISCERATION).

During the year 1896 I performed twenty-eight operations at the Medico-Chirurgical Hospital.

In regard to this operation I do not know that I can add any original point or suggestion to what I have already stated elsewhere. As time goes on and my experience becomes greater the more firmly am I convinced that ophthalmic surgery has been much benefited by adding this operation to its list, and like Brudenell Carter, I may say that "I am performing it with increasing pleasure on every available occasion."

Dr. Mules has given us the following table, which shows the advantage of this operation over that of enucleation:

ENUCLEATION	VERSUS	MULES' OPERATION.
1. Complete removal of globe and its contents.		1. Retention of the framework of the eye.
2. No stump, therefore sunk-in eye.		2. A firm, round globe forming perfect support for artificial eye.
3. Disturbance of all muscular relations and arrest of movement.		3. Perfect harmony of muscular movement retained.
4. A fixed staring eye attracting attention.		4. Fitted with selected eye defects detection.
5. Patient shuns society.		5. No qualms as to personal appearance.
6. Arrested development of orbit in case of children.		6. No interference with growth of orbit.

Mr. T. Herbert Bickerton of Liverpool, who has had the largest experience in England, always prefers evisceration to enucleation. In a recent letter from Mr. Bickerton he states that he is substituting silver balls for glass ones. Since January of this year I have also substituted silver balls, not for the reason that any change is made in the technique of the operation, but simply that no possible danger could arise of the breaking of the silver ball, which might remotely happen to a glass ball.

I repeat my method of performing this operation: The eye is thoroughly irrigated with a lotion, which I call formula No. 1¹ to designate it from almost the same formula for sterilizing instruments.

The eyelids are separated with the ophthalmostat. The conjunctiva is dissected off from its corneo-scleral attachment back to about the equator of the eyeball, the muscles also separated; then the cornea is excised. This is best done with a large Beer knife, as if performing a flap operation for cataract, the lower half of the cornea is removed with curved scissors, and the contents of the globe are taken out with a small scoop devised for the purpose.

Great care is necessary to remove the ciliary bodies and choroid and the head of the optic nerve, leaving a clean white sclera. Mr. Carter has devised a rubber bulb which is inserted into the scleral cavity and inflated with air to produce pressure on the central artery to prevent hemorrhage. As this application has not been a success with me, I pack the scleral cavity with sterilized gauze. After waiting a few minutes this is removed, and the contents of the scleral cavity are again thoroughly irrigated with antiseptic fluid and again packed. A sterilized glass globe, which is best suited to the case, is then inserted with a specially devised instrument. The sclera is split

vertically so that the edges may be drawn together and held by stitches of No. 4 black silk, using large needles, completely hiding the glass ball. The orbit is again thoroughly irrigated with the hot solution and the socket packed with sterilized gauze. This dressing is kept wet day and night for twenty-four hours, when the eye is bathed with hot water and fresh dressings applied and continually saturated with the lotion, over which is bound a sterilized bandage.

At the end of twenty-four hours the upper eyelid is somewhat swollen, puffy and edematous, but the tumefaction gradually disappears. As a rule, the conjunctival sutures are not removed under six or ten days. It is important that both eyes are kept bandaged for at least six days. By allowing the liberty of one, too much rotation of the eye is permitted and, as a consequence, the antagonistic muscles of the operated eye pull apart and there is greater pressure brought against the sutures, which are liable to be torn out, a probable cause in several of my cases.

From the large number of operations now under observation, and no unfavorable ones reported, it may be considered a very safe one, and if we have in evisceration a method equally as safe as in enucleation, why not give the patient the advantage of the new method.

Résumé.—The total number of operations performed up to the present writing numbers eighty-two, and so far as I have been able to keep trace of them no serious results have followed any, such as sympathetic irritation or meningitis. In two cases the glass ball came out after two months. I have eight cases which did not heal by first intention and the balls came out before the patients left the hospital. I must attribute these failures to too rapid absorption of the catgut, or the glass balls being too large and the swelling of the tissues causing the silk to cut through the sclerotic and conjunctiva.

1304 Walnut Street.

AN EXPERIMENT ON A RABBIT'S EYE, TO OBTAIN AN ELASTIC, UNBREAKABLE "ARTIFICIAL VITREOUS BODY" AFTER EVISCERATION.

(MULES' OPERATION.)

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY ALBERT PICK, M.D.

BROCKTON, MASS.

Dr. J. Herbert Claiborne of New York City presented a paper on this subject at the Forty-seventh Annual Meeting of the Association, at Atlanta, Ga., at which he described his experiments and drew conclusions on the subject. After reading his excellent paper (*JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, Nov. 21, 1896, p. 1091) I was stimulated to try an experiment in this direction.

It is conceded by ophthalmologists that enucleation does not leave a sufficiently prominent and movable stump in the socket to afford the accurate and comfortable fitting of glass eyes. The objection to the introduction into the eviscerated scleral cavity of Mr. Mules' glass balls are that they subject the ciliary nerves to a constant pressure between two hard and unyielding surfaces, that glass balls are subject to fracture and that they are difficult of introduction.

IRRIGATING FLUID.

Hydrarg. bichlor	grains 1 50.
Zinc sulphocarbolic	grains 30.
Aq. menth. pip.	drachms 2.
Aq. camph	
Aq. destil	aa ounces 2.
M. ft. sol.	

The same lotion without the hydrargyrum is used for sterilizing instruments.

Dr. Claiborne in his conclusions says: "The implantation into the scleral cavity of some soft yielding body which will not degenerate, which can be rendered aseptic, which will not swell by imbibition and which will not become absorbed, seems to be a rational procedure." Following out his line of thought, it occurred to me that a soft rubber ball, rendered aseptic, would possess these requirements. I had, therefore, made for me, soft rubber balls of various sizes.

Experiment.—On April 10, under anesthesia and perfect aseptic precautions, I eviscerated the eye of a rabbit. After cutting away all the cornea and separating the conjunctiva from the sclera around its corneal edges, I made two small vertical cuts in the sclera, one up and one down. The last procedure had for its object to permit the easy introduction of the rubber ball, without the aid of any special instrument. The introduction of the small rubber ball was easily accomplished, after which the incisions in the sclera were closed by fine catgut sutures and the wound edges of the conjunctiva closed by fine silk sutures.

The animal and the wound seemed to do well, but unfortunately the rabbit, which I had out for an airing on the fourth day, was accidentally killed. On postmortem examination the wounds seemed to have well progressed in the process of healing by first intention and the small rubber ball was in its proper place. I had intended to save the animal until shortly before this ASSOCIATION meeting and then examine the condition of the rubber ball and eye socket. I suppose an objection will be raised as regards the stability of the rubber within the eye-socket, it being constantly acted upon by the secretions. This is exactly the point which I had intended to investigate had the animal not been killed. I therefore tried to imitate the natural process and I placed the small rubber ball in a weak saline solution (not sterilized) in which I have left it for about two months, supposing that a saline solution would most closely resemble the natural secretions within the eviscerated scleral cavity. The rubber ball has undergone no change. I have seen soft and hard rubber appliances (rings, pessaries, etc.) left in the vagina for years which were very little, if at all, affected in their structure. [Rubber balls were exhibited at the Meeting.]

Although this may not be the ideal "artificial vitreous body" or, rather, artificial intra-ocular body, I trust it will be another stepping-stone toward finding such a one, which will remove all objections by ophthalmologists to Mr. Mules' glass balls and operation and will make more general and safer, in suitable cases, the operation of evisceration, which certainly yields a better stump and greater satisfaction to the oculist and patient.

The balls were made for me by Geo. Tiemann & Co. of New York City, whom I must thank for their assistance and generous expenditure of time and money for the molds to make the balls. They also made some hard rubber balls which might be preferred to glass balls for those who would rather use them. Dr. Wm. H. McKibben of Cincinnati kindly assisted me in the operation.

DISCUSSION.

Dr. FRANK ALLPORT of Chicago—I had the pleasure of witnessing Dr. Fox make some of these operations last fall, and I thought them as near perfection as possible. I have not made any of the implantation operations of which he speaks, but as I have seen some of the results which have

proceeded from his clinics, I can testify to their value. The insertion of a Mules' globe within the scleral sac as a substitute for eyeball enucleation is a procedure against which I have always been prejudiced, and it was not until I had the pleasure of seeing Dr. Buller of Montreal, and Dr. Fox of Philadelphia, perform the operation, together with the observation of the results of past operations, that I surrendered my prejudices and consented to offer this method of relief to my patients. I have operated on a number of these cases since last fall, and although my cases have uniformly yielded favorable results, the time is as yet too short to estimate their permanency; but I for one am willing to accept the testimony of well-known surgeons who have kept cases under observation for many years and are still able to endorse this procedure. The operation must, of course, be performed with rigid antiseptic precaution, as otherwise absolute failure will almost inevitably result. Great caution should be observed in the complete removal of all traces of those elements constituting the ciliary region, and as an extra precaution, I usually trim off the edges of the scleral wound in order to remove the little scleral ridge at the scleral corneal junction, underneath which may sometimes be observed traces of the ciliary body. The protruding optic disc should always be carefully smoothed down to a level with the inner surface of the sclera, in order that the glass globe may not prove an irritant to its fibers. The little shovel-shaped scoop that has been devised for the purpose of eviscerating the contents of the globe, while especially adapted for this purpose, is not essential, as any medium-sized scoop will answer the purpose as well. I have used a large sharp-edged mastoid scoop for the purpose with perfect satisfaction.

The same may be said of the instrument devised for picking up the glass globes and inserting them into the scleral cavity. The instrument is useful but not essential, as the globe may be inserted with equal facility and safety by the surgically clean fingers. The hemorrhage which occurs in the course of the operation is sometimes troublesome, but is easily controlled by the use of very hot bichlorid tampons, which are also useful in all operations where troublesome hemorrhage is liable to occur.

I think one reason why some gentlemen complain of a subsequent escape of the glass globe is from the fact that they did not use a sufficient number of sutures. I have heard of some gentlemen saying that they used three or four sutures in closing up the scleral gap. I use as many sutures as the scleral tissue will accommodate, sometimes inserting as many as seven or eight, carefully setting them well back from the edges and, so far as my own experience is concerned, have never been troubled with their pulling out. I have used both black silk and catgut sutures, but prefer the former because I believe them to be more trustworthy. The globe which is inserted should not be too small nor too large. Both extremes have their disadvantages. If the globe is too small it will afford but a scanty support for the artificial shell which is subsequently inserted, thus diminishing the cosmetic effect of the operation. If it is too large it operates unfortunately in the inevitable swelling and inflammation, which can always be depended on in varying degrees. The globe should be just large enough to comfortably rest within the scleral sac and allow a moderate degree of wrinkling and laxity of its tissues over its glass surfaces. When thus, by the use of a globe of proper size, abundant contact between the artificial shell and the sclera is produced, the artificial shell is forced into a natural and prominent position, thus admitting of a harmony of motion between the two bodies. The reaction following the operation is somewhat excessive, but so far as my own experience is concerned, has never been uncontrollable, although in one case I confess I was tempted to remove the globe. I have controlled such reaction by the use of a lotion, recommended by Dr. Fox, consisting principally of arnica, opium and lead water, which I keep on ice and freely use.

I have found it exceedingly difficult to procure artificial eyes which are adaptable to these cases. The eyes which are on the market at present have been manufactured with the old enucleation operation in view and with the idea of filling out a hollow orbital cavity. All that is necessary for a socket upon which a Mules' operation has been performed, is a broad flat-tish shell, but these are hard to find. But if the Mules' operation attains the position which I believe its surgical importance demands, this difficulty will no doubt be obviated by the manufacturers.

I desire to thank Dr. Fox for his most excellent paper and for the good work he has accomplished in this line of surgery, and to say with him that I believe the operation to be a justifiable one, and if this is true, it should become generally used, as it is incomparably superior to any operation with which we are familiar and, in fact, may be said to be as nearly ideal as

possible. I have had no experience in the use of any globes except those of Dr. Mules, but I believe, in a general way, that the glass globes, although subject to the very remote possibility of breakage, are of the best material that can be used.

Dr. S. D. RISLEY of Philadelphia—Notwithstanding the adverse criticisms which have been urged against this operation by some surgeons whose ability gives great weight to their opinions, I am convinced that it is not only a justifiable and highly interesting operation, but one to be commended in prudently selected cases. It probably should never be allowed, however, to supplant excision of the globe in an extensive group of cases. For example, in suspected malignant disease of the intra-ocular membranes, in suppurative panophthalmitis, and in case of a retained foreign body when there is a probability of its lodgment in the orbit after passing through the eyeball.

Two years ago I reported a case of this kind and now present the mounted specimen, where the foreign body is seen clinging to the posterior pole of the ball near the optic nerve entrance, having penetrated all the coats. In a large number of patients, however, the operation is proper and presents many advantages over enucleation in securing the comfort and satisfaction of the individual. In the first place the deformity is much less than after enucleation. If the glass ball selected is of suitable size, in place of the unsightly empty orbital socket there is very little depression of the lids. It is open to question, however, whether the surgeon should for mere cosmetic results undertake a more difficult and tedious operation followed by a more uncertain convalescence. But the absence of deformity is by no means the most important of the results following the Mules operation. The empty socket, in most patients where the enucleation has been performed, is not only a reservoir for the accumulation of tears and mucus and dust, but forms an excellent nidus for dust and micro-organisms. There is in consequence a persistent mucopurulent discharge, causing the constant necessity for the use of aseptic washes. The artificial eye is also a constant source of annoyance. It must be frequently removed not only for cleansing but to relieve a source of irritation and discomfort. The artificial eye is hemispheric in form, the concavity being backward, the edges of rim resting on the tissues of the orbit. These tissues are more or less saucer-shaped, the concavity being forward so that when the shell is *in situ* an almond shaped cell is formed, at first filled with air, which soon absorbs, leaving a vacuum behind the shell. The atmospheric pressure upon the surface of the glass shell is then sufficient to cause discomfort and edematous swelling of the conjunctiva included within the rim of the concave shell. The truth of this statement is demonstrated by the considerable force often required to lift the artificial eye out of its bed, which is attended by a slight hissing noise as the air rushes behind it. This pressure is the explanation of the thickened and edematous condition of the orbit so frequently seen when the eye has been worn too continuously. Now, after the insertion of the glass ball in the emptied sclera the orbit no longer presents a concave, but a convex surface which is concentric with the concave surface of the artificial eye, so that no vacuum exists if it has been properly fitted. If of suitable size it also moves to and fro, up and down, in excursions which more nearly approximate those of the fellow eye than after enucleations, since the intra-ocular muscles have not been disturbed at their points of insertion to the sclera. In my own cases, even without the artificial eye, the tears and mucus do not accumulate but flow off by their natural channel and there has been no tendency whatever to inflammation of the conjunctiva. The patients have also been able to wear the artificial eye more continuously without harm resulting than after enucleation.

As regards the technique of the operation it has been my habit to make the line of the sutures horizontal instead of vertical, as has been done by some surgeons. The first step of the operation is to detach the conjunctiva about 5 mm. back from the corneoscleral junction. A Beer's knife is then inserted on the horizontal meridian about 5 mm. from the cornea, and the counter puncture made at a corresponding point on the opposite side of the ball, the knife entering behind the iris, the complete incision simply including the root of the iris above. The upper edge of the flap is then grasped with the forceps and a corresponding incision made below with the scissors. Much time and annoyance is then saved by grasping as gently as possible, with broad forceps, the ciliary body and carefully detaching the entire uvea with the flat handle of a scalpel. Then grasp it at its attachment in the region of the optic nerve, when the posterior scleral vessels may be torn away and the entire contents of the ball removed with comparatively little difficulty.

After the bleeding has ceased a glass ball should be chosen,

as large as will nicely fill the scleral cavity. If it is too small there will be much overlapping of the scleral wound when the sutures are tied. I prefer for the sclera fine carefully sterilized catgut sutures, which should be placed at least 5 mm. back from the edge of the scleral opening. I regard this deep placing of the scleral sutures as of great importance, of which there should be at least five and a like number of fine, black silk sutures placed in the conjunctiva, closing it over the scleral wound.

In my earlier experiments my patients suffered greatly from extreme edema of the lids and chemosis of the conjunctiva which I think is caused by the extensive interference with the anastomotic circulation. In my later cases a firm compressed bandage has been applied and allowed to remain undisturbed for two days. In the first case thus treated, the edema and chemosis were greatly reduced; in the last case absolutely prevented. I have been struck with the rapid recovery following these operations; in every case it has been possible to introduce the artificial eye, and permit it to be worn with practical impunity at the end of two weeks, and in one case this was done on the tenth day. To secure the best results after this operation an artificial eye with a larger radius of curvature than those usually found in the market is required.

Dr. G. ORAM RING of Philadelphia—There can be no question but that the operation of "evisceration of the eyeball," with the insertion of an artificial vitreous, after the method of Mr. Mules, has taken a permanent place in the list of legitimate and important ophthalmic operative procedures; but, while I wish to be recognized as an enthusiastic advocate of the operation in suitably selected cases, being quite in accord with Mr. Brudenell Carter, whom I quoted in my review of the subject over two years ago, as believing the profession indebted to Mr. Mules for one of the most remarkable and valuable improvements in modern ophthalmic surgery, I still do not believe that the method should by any means be regarded as an universal substitute for the classic enucleation.

Although the introduction of the Mules spheres was suggested about twelve years ago, it has only been during the past two years that American ophthalmologists have accorded to the subject its merited attention. Our text-books, with one or two exceptions, have been silent regarding more than the merest superficial consideration of it, and the JOURNAL reports from the various operators have been far too infrequent. I believe all the surgeons who perform the operation frequently, have an increasing confidence in its utility. We can only arrive at a proper appreciation of the place the operation should hold by a careful, but not necessarily lengthy, publication of each failure, as well as of each success. Perhaps quite as important will be the publication of the detailed histories of those cases in which the operators have carefully considered, in each instance, the respective merits of the Mules operation, as compared with enucleation, with the reasons for the decisions in favor of the enucleations.

It is well known that at the recent meeting of the British Medical Association, in Carlisle, Mr. Bickerton of Liverpool accorded very high praise to the Mules operation. I had an opportunity, during the past summer, of examining a number of Mr. Bickerton's cases, and his beautiful results fully justify his enthusiasm. I therefore can not accord with Dr. Castillo in his recent criticism of this paper, and believe his conclusions, that only leucomatous eyes are adapted to the Mules operation, to be erroneous.

In a recent number of one of the Vienna journals (*Wien. Klin. Woch.*), Pfleger states that in order to prevent sympathetic ophthalmia, enucleation is the only proper operation. In three of my eviscerations, with the insertion of artificial spheres, distinct symptoms of sympathetic irritation were present. One was performed two and a half years ago, a second a year ago and the third six months ago. They all did well, and the irritated eye has in each case remained perfectly quiet. It has been thought by some of the operators (I think Dr. Fox and Dr. de Schweinitz are among the number), that calcareous degeneration of the interior eye tunics constitutes a contra-indication to the Mules operation. I performed the operation in a very pronounced case of the above type, during the winter, with a perfect result.

I will briefly refer to two recent cases, in both of which I decided on enucleation rather than the Mules operation. The one an acute inflammatory glaucoma in a patient 70 years of age, with organic valvular disease; the eye having been quiescent, but blind from a retinal detachment for about one year previous to the development of acute symptoms. The infiltration of the lids and peri orbital tissue became so intense that fears were entertained for a suppurative inflammation surrounding the eyeball. This condition of affairs, coupled with a marked lowering of the patient's vitality, and the importance of an immediate removal of every possible source of further

systemic depression, decided me in favor of the enucleation. The case occurred in private practice and was seen in consultation with Dr. W. F. Norris, who concurred in my opinion. Post-operative senile dementia followed the operation, the mind becoming entirely clear with returning strength; no local complication followed.

The second case was one of inflamed scleral staphyloma, with beginning sympathetic irritation. I had intended in this instance to do a Mules operation, but upon dissecting the conjunctiva from the globe found such pronounced scleral distension and attenuation that the eyeball, when freed from the conjunctival attachment, immediately protruded so far forward that I was inclined to fear a possible growth in the posterior portion of the orbit. This did not prove to be true. This excessive protrusion with such striking distension and attenuation constituted, in my judgment, sufficient reason for not risking the introduction of an artificial vitreous.

I am still using catgut sutures for stitching the sclera in the Mules operation and silk sutures for the conjunctiva.

Dr. J. L. THOMPSON of Indianapolis—I wish to speak of some of the conclusions and of the comparison of the two operations. Some of the gentlemen have spoken of the fixed condition of the eyeball and of patients shunning society after enucleation. Have many of you found fixation of the eyeball after enucleation, unless there was atrophy or in burns of the eye? And the question in such cases is whether you would accomplish much more by this operation. I must have seen several hundred cases of enucleation and I have not noticed this staring appearance; I should not expect to see it unless the operation were done with a pair of sheep-shears or by some one who knew nothing about it. I think after you had as many cases of this operation as we have of the older one, you will find a great many cases of failure.

Dr. J. C. DUNLAVY of Sioux City, Iowa—The fitting of an artificial eye is one of two objections to this procedure. The implantation of a glass ball places the thin tissue continually between two glass surfaces. It appears to me that the tissue can only last a certain length of time and sooner or later will be destroyed. The staring eyes referred to after enucleation is to me one of the greatest horrors. In late years I never enucleate an eye unless absolutely compelled to, to save a fellow eye; if I can not do anything else I do the ordinary evisceration and find the small stump left is preferable to removal of the entire globe. I have never seen any reason for this staring except that the artificial eye does not fit. Rubber balls instead of glass ones appears to me to be impracticable, for I should consider that they in time would be destroyed.

Dr. S. C. AYRES of Cincinnati—I would like to mention an unique experience in the use of these balls. I was in London and bought a few of them when they first came out. A short time after, Dr. Sattler had occasion to use one of them. The operation was done properly, but two or three days later irritation set up and the stitches had to be taken out and the ball removed. We found a little pus in the glass ball; it had been a defective one with a little opening in it and had excited the trouble. It only serves to show what the possibility might be in the use of a glass ball, and I should think a silver ball might be better.

Dr. A. E. PRINCE of Springfield, Ill.—I have been using the glass balls for about twelve years and have not had very great success with them. In one case out of a series of six there was a splendid result; the other five failed. Now the silver ball has been spoken of and there is a point in general surgery that must be universally known, and that is that silver when in contact with granulating tissue becomes coated with lactate of silver, which is demonstrated to be a good antiseptic. Now if we use the silver ball and lactate of silver is formed, we have generated an antiseptic that may prevent failure in such cases as Dr. Ayres suggests, whereas in case of the glass ball the result would be disastrous.

Dr. GEORGE FRIEBIS of Philadelphia—I have had but little experience with the Mules operation. I had more with enucleation, but the Mules operation in all suitable cases will undoubtedly give far better results so far as cosmetic effects are concerned, and as has been emphasized, that is one of the principal points to be considered. The cases must be properly selected, but in many cases the Mules operation is one of superiority over enucleation because the motility of the eyeball is almost equal to that of the sound eye. I have seen several cases of enucleated eyeballs that presented the staring appearance undoubtedly. One that I performed some time ago, and I think I performed the operation with a fair degree of skill, presented considerable reduction or retraction of the ball, and that in itself is a cause in many instances of that staring condition that I detect after enucleation and which is absent after the Mules operation.

Dr. L. W. FOX of Philadelphia—I wish to call more attention to the implantation of the glass ball than to the Mules operation, which will take care of itself. The gentlemen who saw the operation of implantation yesterday saw that it would have been impossible to adjust an artificial eye, and it is in such cases that implantation is of the greatest value. It produces a bulging out of the stump upon which an artificial eye can operate. My first three cases were cases of a similar character, performed in 1895, and they have since been wearing artificial eyes with good adjustment and good movement. It is not as good as in the Mules operation, but better than complete enucleation. The case on which I operated yesterday was shown to six or eight of the gentlemen today, and the reaction was very slight; I am sure they were all surprised. Had not the gentlemen been there today I should have kept the bandage on for two or three days, as I find that a great improvement; I called attention to that point in my last paper. As regards the glass ball carrying infected or septic material into the eye, all the glass balls I have been using were sterilized in boiling water and if they are defective the water finds entrance into them and I throw them away.

Dr. ALBERT PICK of Hyannis, Mass.—In answer to Dr. Dunlavy's objections I would say that I simply tried this experiment for the sake of finding an elastic, unbreakable, aseptic substitute for Mules' glass ball, and that the rubber, hard or soft, will not degenerate as easily as the Doctor thinks.

BACTERIA IN THE NORMAL CONJUNCTIVA AND THE EFFECT UPON THEM OF ASEPTIC AND ANTISEPTIC IRRIGATIONS.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY ROBERT L. RANDOLPH, M.D.

BALTIMORE, MD.

The works of Leber, Sattler, Gifford and others on the bacteria of the conjunctiva are practically in accord in the opinion that the conjunctiva always contains bacteria. I recently made a series of experiments upon 100 individuals. These 100 persons comprised patients (not eye patients) in the dispensary, nurses, medical students and others. The inoculations were on nutrient agar, and usually smear cultures were made. A platinum loop was sterilized by passing it through a flame, and it was rubbed over the lower part of the conjunctival sac. The patient was then made to look down and the loop was carried well up into the upper part of the sac, and finally rubbed gently over portions of the bulbar conjunctiva. It is hardly practicable to bring the loop into contact with every part of the conjunctiva, and I doubt whether the platinum loop ever touched more than half the conjunctival surface, and yet out of the 100 cases there were only thirteen sterile tubes. If then inoculations from a limited area of the conjunctiva show the presence of the bacteria in eighty-seven out of 100 cases, it is more than probable that inoculations from the whole conjunctiva would show the latter to invariably contain bacteria. One must be careful in this class of experiments to avoid touching the eyelashes or the free border of the lids, as contamination will certainly result. In eighty-five out of the eighty-seven cases where bacteria were found, the latter resembled each other morphologically. No effort was made to determine the properties of this organism, and nothing can be said of it further than that it looked like one of the pyogenic cocci.

In surgery two methods are employed to sterilize the field of operation: The aseptic method, by which bacteria are removed by mechanical means (as for instance, the irrigation of a point with water which

has been sterilized by heat), and the antiseptic method consisting in the employment of chemicals which have the effect of either destroying bacteria or of interfering with their growth. Both methods were tested in two series of fifty experiments each. First the aseptic method: Inoculations were made from individuals with normal conjunctivæ. After this the conjunctivæ were irrigated three times (with an interval of five minutes between each irrigation) with water which had been sterilized by boiling, and inoculations were made from them again into agar. There was a growth in forty of the tubes representing inoculations before the employment of the aseptic irrigation; the other ten tubes were sterile, and hence are not counted in the results. After the aseptic irrigations there was a growth in thirty-two tubes, that is to say the apparent effect of the aseptic method was to produce sterility of the conjunctiva in eight cases out of forty. It is evident from this that we can not rely upon aseptic irrigations of the conjunctiva to produce sterility of this membrane. Another series of fifty experiments were then made. Inoculations were made to see if the conjunctivæ contained bacteria, and immediately afterward these conjunctivæ were flooded with a sublimate solution 1 to 5,000. Five minutes later inoculations were made from them again. Before the use of the sublimate forty-two tubes presented growth and eight were sterile. The eight are excluded. In the forty-two cases where there was a growth before the instillation of the sublimate there were nine sterile tubes after the use of this solution. The same staphylococcus which was so constantly found in the first series, was also found in the second and third series, and in the last twenty-five cases this organism was subjected to this test. The end of a platinum loop, after being thoroughly rubbed over the growth, was immersed in a solution of sublimate 1 to 5,000, and allowed to remain there for five minutes. The loop was then withdrawn and plunged into agar, and in every case there was a luxuriant growth, a result which showed that the chemical had apparently no effect on the vitality of the organisms.

Both aseptic and antiseptic methods then in my hands led to practically the same results, for by neither method was sterility of the conjunctiva obtained. I have frequently observed that persons complain of a biting sensation in the eye after an instillation of sublimate solution, and in my experiments hyperemia of the conjunctiva was produced a number of times, so I am inclined to think, in spite of what Franke has said on this point, that such solutions are more or less irritating in their effect on the conjunctiva. All that can be said of such a solution is that it may deprive the conjunctival bacteria of some of their virulence, in other words render them less effective, and then again it may actually kill some of the more superficially situated bacteria. It is more than probable that the conjunctival bacteria are so firmly attached or imbedded in the conjunctiva as to be beyond the reach of either the aseptic or of the antiseptic method as practiced by ophthalmologists, and nothing but the most vigorous scrubbing would produce asepsis.

The experiments reported here show that in so far as the conjunctiva is concerned, little reliance can be placed on the usual methods employed by ophthalmologists for obtaining asepsis.

Conclusions.—The normal conjunctiva always contains bacteria. It is probable that the bacteria found in this locality are usually of only slight, if any, path-

ogenic character. It should be remembered though, that bacteria ordinarily non-pathogenic may become harmful under certain conditions, that is if the tissues are bruised by the instruments or irritated by chemicals. Neither the irrigation with sterilized water nor the instillation of a sublimate solution (1 to 5,000) produces sterility of the conjunctiva, and inasmuch as both measures are futile and possibly harmful they may just as well be abandoned. These methods of sterilizing the conjunctiva are the ones usually employed by ophthalmologists, and hence the choice of them for testing this question. It goes without saying that a method which would destroy the bacteria of the conjunctiva without at the same time impairing the integrity of this membrane would be a great advantage. In operating upon the normal conjunctiva as in cataract operations, the surgeon in the present state of our disinfecting armamentarium would do well to consider the subject of antiseptics and asepsis chiefly if not solely in connection with his hands and instruments, and of course the cocaine and atropin.

DISCUSSION.

Dr. HAROLD GIFFORD of Omaha—With these conclusions of Dr. Randolph I agree almost entirely. I have made this thing something of a study and I have found it practically impossible to sterilize the sac, as I believe everybody has found. That in some cases the normal conjunctiva has been found sterile, I think we can attribute to the method used in trying to find out whether bacteria are there or not. Now if you consider the effect of trying to get bacteria by wiping a wire loop around the conjunctiva you will see that you may get some few perhaps at one point and then wipe them off at another, and so perhaps get none. To me, the best method of testing this subject appears to be that of Bardelli, who after separating the lids widely with a speculum filled the sac with soft gelatin. Leaving this in a few minutes and then withdrawing by a pipette he made it into a plate, and by this means the conjunctiva has never been found sterile.

Now as to the reason why we can not sterilize the conjunctival sac. As Dr. Randolph has said, the skin has been shown to be impossible of complete sterilization without complete removal of the epithelium, and even that may fail. The conjunctiva is so smooth a membrane you would expect to sterilize it by wiping it well, but even if you remove all on the surface the germs from the crypts will come out and multiply and you have the same condition as before. Even if you could temporarily sterilize it you could not rely on the condition existing more than an hour or so after closing the lids and applying the bandage. Moreover, in attempting to get this much-desired asepsis, we run the risk of doing more harm than good, for in using these agents you may irritate the tissues so that the bacteria that are left will proceed upon the favorable conditions left, denuded epithelium and increased blood supply, and in twenty-four hours you have a worse condition than if nothing had been done.

Just one point I would like to insist upon where I differ with Dr. Randolph, namely, that we should pay all attention to the asepsis of the hands and instruments. We do not rub the eyes with our hands, but the instruments are of extreme importance. As we are not certain of getting all the germs away from the eye before passing any instruments into the eye we should wipe off the eye with a sterile swab. I wipe off the immediate surface with a sterile swab the instant before inserting the instrument.

Dr. J. E. WEEKS of New York—I think it would be unfortunate if the impression should go out that we must forego all attempts to render the conjunctival sac as clear of bacteria as possible. It is well known that the majority of bacteria found in the sac are innocuous. I have done considerable work in that line myself, and from the normal conjunctiva I have isolated ten or twelve distinct varieties of micro-organisms, of which only two or three were pathogenic. There is another thing we should bear in mind and that is that the bacteria there present may be pathogenic and yet create no disturbance unless they are present in large quantities. We can so lessen the number of micro-organisms present that they will be relatively harmless. We find some excretions from the lachrymal sac that escapes the casual observation, and if they are thoroughly washed out we have no trouble from them, but if no attempt is made to cleanse the sac we shall have trouble. I

think the attempt to cleanse the conjunctival sac has done much to increase the number of successes in operation upon the eye. To advocate the cessation of these attempts would return us to the bad results given before antiseptics was instituted. It has been my practice ever since my studies began to use an antiseptic solution; I have used the bichlorid in strength of 1 to 5000, frequently boric acid solution, and I have yet to regret the use of those solutions, and have congratulated myself on its use in many cases where I am quite sure I should have had trouble if I had not used it.

The experiments Dr. Randolph has described are very excellent in many respects. In the use of the loop to expose the micro-organisms to a 1 to 5000 bichlorid solution for five minutes, he certainly introduced a mass of bacteria that could not be effectually reached by the solution in that space of time, and there are few who would claim that the death of these organisms would be brought about by such exposure.

Dr. A. R. BAKER of Cleveland—I can not contribute to the pathologic study of the subject, but I have thought for many years that the bacteria present could not be washed away, and that probably if they were we should do harm in the efforts. I have my patients come into the hospital the day before the operation, thoroughly cleanse the eyelashes and lids, remove all loose lashes, scrape the lids thoroughly, as I would in preparing for operation in any other part of the body, apply a sterilized bandage and leave it on over night, and if the lids show any secretion in the morning I leave it without operation until I can bandage the lids over night and have no secretion, and so I exclude the possibility of having any large number of micro-organisms present.

Dr. MYLES STANDISH of Boston—I agree with Dr. Randolph as to the necessity of cleansing the lids, but we must remember one other source of infection, however, and that is the tear sac. The question whether we have a tear-sac distended is one of the greatest importance, and the first thing to discover is whether we have a prolific source of irritation in that region.

Dr. F. C. HOTZ of Chicago—I only wish to say a few words in regard to cleaning the retrotarsal fold preparatory to operations. It is difficult to reach all parts of the upper folds. I have seen it attempted by passing the nasal syringe or the eye dropper under the lid and expecting to flush the folds sufficient to cleanse them as well as we can, and I think a better method is to turn the lid, and fixing it with the thumb of one hand, pass the lower lid over the eyeball and press it back into the orbit. A slight pressure fully exposes the fold and you can wash it very successfully.

Dr. LUCIEN HOWE of Buffalo The remark I would make is *apropos* to Dr. Hotz's remarks, that the great difficulty is in reaching the retrotarsal fold. I have followed an excellent device for some time, the credit for which belongs to Landolt, which consists of a glass button with a tube entering near the center. This button is put under the upper lid and by holding in this way [demonstrating] the fold is brought out and can be flushed thoroughly. He recommended it first for flushing the eye in ophthalmia neonatorum, but it is excellent for general use.

Dr. ROBERT L. RANDOLPH of Baltimore—The point which Dr. Weeks has made is a good one. It is quite possible that the entire mass of organisms was not penetrated by the sublimate, but I should have added that this identical organism has been subjected to the usual tests at the hands of others and found to retain its vitality after immersion in sublimate solutions, so that the facts are as I have stated them, namely, that the organism which is to be found so often in the normal conjunctiva is proof against the germicidal action of sublimate in the strength employed by ophthalmologists.

has been the means par excellence long recognized for destroying bacteria. Specially devised droppers, as Stroschein's¹ and Llewellyn's bottles, in which the solutions of mydriatic or myotic can be boiled before use, are satisfactory, but unless a cap is provided for the exit tube, or the tube itself has a bend that serves as a trap and keeps the solution in the bottle free from dust, there is always danger of contamination of the solution upon repeated handling. Even if the bottle is provided with such a trap, the solution which collects in it should be removed each time before use by gently flaming the tip, or by the use of disinfectants. The mere forcing of more solution through the unsterile tube will suffice to contaminate the contents of the flask.

I have had a flask made which with very little trouble appears to obviate this danger. After use the tip of the bottle may be dipped in a 1 to 1,000 trikresol, or 1 to 5,000 formalin solution (either of which could be conveniently kept in a low, wide-mouthed bottle) when sufficient liquid will be drawn in to fill the bend and serve to seal the flask and prevent the entrance of germs from the air. When the flask is to be used the first few drops of liquid may be wasted and the tip dipped again in the 1 to 1,000 solution to destroy any germs adhering to the outside. These flasks may serve for solutions sterilized by heat or chemicals. Methods of chemic sterilization, or a combination of chemic sterilization and boiling are better than boiling alone. As has been pointed out by Franke,² G. de Schweinitz and the writer,³ and others, the use of boric acid for the purpose of sterilization is unsatisfactory, as its germicidal properties are much less than were originally supposed. The objection to mercuric salts lies in the strength as well as the poisonous properties of the solution which should be used to insure complete sterilization.

Credé⁴ has pointed out the value of the acetate and lactate of silver as germicides, and the idea suggested itself that these salts might be useful in sterilizing collyria if they would not be too easily decomposed, but the ready precipitation of the metallic silver made them useless for this purpose. The ever faithful carbolic acid has been largely replaced by trikresol, the latter being less poisonous and more efficacious in weaker solutions, and as the writer⁵ pointed out in 1894, collyria made up with a solution of 1 to 1,000 remained thoroughly sterile under the most adverse conditions, and were not irritating to the eye. Upon writing to five prominent ophthalmologists, I learned that only one had used trikresol in place of carbolic acid, but he reported very satisfactory results. It so happened that I had left the solutions used in my original experiments three years ago, in a closet by my working table, and recently I tested them to see if they had become contaminated. One of the bottles

THE BEST METHODS OF STERILIZING OPHTHALMIC INSTRUMENTS AND SOLUTIONS OF MYOTICS AND MYDRIATICS.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. A. DE SCHWEINITZ, M.D.

DIRECTOR BIOCHEMIC LABORATORY, DEPARTMENT OF AGRICULTURE; DEAN AND PROFESSOR OF CHEMISTRY, COLUMBIAN MEDICAL COLLEGE.
WASHINGTON, D. C.

That process of sterilization is of course the most useful which gives the best results and can be most quickly carried out, as boiling, where it is convenient,

still contained about 5 c.c. of the eserin solution, while the water had almost entirely evaporated from the others, showing that the bottles were but loosely corked and access of dust was possible. The contents of these bottles were tested again and found free from bacteria. Pergens,⁶ in 1891, recommended the use of tablets containing a sufficient antiseptic. Valude⁷ and Burnett⁸ have recommended formalin for preserving collyria and instruments. According to the latter, 1 to 2,000 formaldehyde solution is not too strong, but as some individuals are more sensitive to the action of this reagent, and as it has been found that much greater dilutions of formaldehyde are in most instances useful, I prepared cocain hydrochlorid 2 per cent., eserin sulphate and atropin sulphate 1 per cent., with 1 to 5,000 solution of formaldehyde. Tested within ten minutes afterward they were found sterile. The dilution was next increased to 1 to 10,000 and, to 10 c.c., five drops of a culture two days old of *pyogenes aureus* were added. Cultures made after twenty minutes showed growth from the eserin solution only, but the next day all were sterile. Therefore, 1 to 5,000 dilution can be relied upon, and even 1 to 10,000 with a little care may be considered safe. Should the solutions become contaminated from the dust, or from contact with an infected pipette, a very few minutes time is all that is necessary for the destruction of the germs by the formaldehyde.

When we turn to the disinfection of instruments we are met at once by another problem, viz., the necessity of perfect sterilization without blunting the edge or tarnishing the instruments.

Randolph⁹ has carefully tested the use of absolute alcohol for this purpose, which is recommended also by de Schweinitz¹⁰ and others, who have found the following process satisfactory: First, sterilization in 98 to 99.5 per cent. alcohol for twenty minutes and then rinsing once in sterile water. Out of 100 tubes inoculated by Randolph, from seventy-five instruments treated in this way only five were found infected. When, however, the instruments were purposely infected with pyogenic bacteria, treated with absolute alcohol for twenty minutes and tested, forty-three out of fifty showed contamination.

While these experiments proved that instruments as ordinarily infected in their case could be sterilized by absolute alcohol, they demonstrated also that where septic material was present a more thorough treatment was necessary. Theobald¹¹ and Lanier recommend washing the instruments in hot running water for a few minutes, while boiling the water, allowing it to cool and then rinsing the instruments in it did not destroy the germs. Formalin has also been recommended for sterilizing instruments, and Alexander,¹² quoting from the clinic of de Buck and Vanderlinden, and his own work, eulogizes its value, advising 1 to 500 solution, which he says does not blunt the instruments nor injure them in any way. To form an idea of the greatest dilution safe and convenient, I tried 1 to 1,000 and 1 to 2,000 formaldehyde solution, and also the gas itself. I used a cataract knife, dissecting knives, and dissecting and hemostatic forceps, the latter on account of their rough edges which would easily retain infected material. It was necessary to leave the instruments which had just been washed in water after a dissection, in a formaldehyde solution of 1 to 2,000 for thirty-five minutes before the sterilization was complete. With 1 to 1,000 solution, ten minutes gave satisfactory results. The edges did not appear to be blunted, nor

was any tarnishing noted during this time. If the instruments were kept in the solution for two hours or more, a slight deposit appeared, but this could be easily rubbed off, leaving the instrument bright and clean. After sterilization by formaldehyde solution the instruments should be dipped in sterile water before being used, to free them from adhering formaldehyde, which might be irritating.

To try the effect of the gas, the use of which has been suggested, on instruments, a small copper drying oven was taken, about 15 c.c. of 40 per cent. formalin solution placed in a dish in the bottom and a small bottle of calcium chlorid introduced to absorb the moisture. It is understood of course that the formaldehyde solution is placed in the box in the first instance some hours before the disinfection is begun, so that the atmosphere may become saturated with the gas. The instruments were washed for a moment in hot water and laid in this oven. Tested after ten minutes they were found sterile. They were then infected with *pyogenes aureus*, placed in the oven, or box, and tested again after thirty minutes and found sterile. The knives were infected with *pyogenes aureus* (by leaving the blade in the culture from one to two minutes), then wiped with dry cotton and, after ten minutes contact with the gas, tested by culture. They showed growth. This test was repeated with the difference that the knives after infection were rinsed in hot water in a dish, wiped dry and then placed in the formaldehyde bath. After ten minutes no growth was noted. Dissecting knives and cataract knives tested in this way were found sterile. The hemostatic forceps required fifteen to twenty minutes for sterilization. In practice, in preparing for the operation, it would be a very simple matter to rinse the instruments in hot water, wipe them dry and place them in a bath of formaldehyde gas. They could be safely left here for hours without injury. A wise precaution in practice might be to rinse the instruments sterilized in this gas, just before use, in sterile water, to remove irritating formaldehyde, though no odor of the gas could be detected upon them. This is perhaps the simplest way of sterilizing the instruments, as they could be laid on a perforated porcelain tray in the box and the tray removed to the sterile water when the operation is begun. Fifteen c.c. of 40 per cent. formaldehyde solution should disinfect a box of one cubic foot for a week or more, and as long as it is closed the odor of the gas is scarcely perceptible. In fact, as the instruments are not injured by the dry gas, they might be kept in it continuously.

In conclusion it seems to me that trikresol, 1 to 1,000, with a separate bottle full to hold and rinse the pipettes, or 1 to 5,000 formaldehyde solution and the described dropper for collyria, and formaldehyde gas for of instruments, are from a bacteriologic standpoint the best methods of disinfection.

DISCUSSION.

Dr. S. M. BURNETT of Washington—In the face of such dem-

onstrations as we have just had, little need be said in regard to this subject. I have had the pleasure of conversing with Dr. de Schweinitz during the time he has been making these experiments, and it seems to me he has offered us the ideal method of dealing with this question. I am particularly satisfied with the report he has made with regard to formaldehyde, because it is carrying out what I thought when I first heard of the use of formaldehyde. It seems to me to possess, in the highest degree, all the essential qualities of a perfect disinfectant. It has not toxic properties and it has a penetrating power that no other disinfectant has. It is certainly something to congratulate ourselves upon that we are now able to lay aside the forms of mercury. They are not satisfactory and we are all satisfied that they are dangerous.

The experiments of Dr. de Schweinitz have proven the value of formaldehyde in disinfecting instruments beyond dispute. We can all have that sort of apparatus in our offices. In regard to the formaldehyde solutions which I first advocated there is some disadvantage because of the evaporation or gas formation, but if prepared freshly that does not apply. Even under those circumstances, however, formaldehyde is vastly superior to anything else we have.

Dr. HAROLD GIFFORD of Omaha—It seems to me there is danger of what I consider by far the most practical method being somewhat neglected. I refer to the action of boiling water. While I have not the slightest doubt that the method referred to is an efficient one, it seems to me there is a source of fallacy that has been to some extent overlooked, namely, that we have not a method of precipitating formalin as we have with bichlorid. When we tried to precipitate bichlorid all the conclusions are found to be fallacious, and to some extent this may be found to apply to formalin. We expose our instruments and after a time put them in the culture room. Now how can we know that there is not enough formalin, in spite of washing, sticking to the instruments to prohibit the growth of germs. Boiling one minute suffices to kill the germ, if care is taken to do the boiling in closed vessels particularly, and if five or ten minutes is given, there is not the slightest danger to the instruments if they have been wrapped in cotton, and you have instruments that are sharp and sterile. Boiling them first and transferring to another solution I consider faulty. Why not take them from the boiling solution and use them at once? That seems to me the simplest method and the best.

Dr. C. F. CLARK of Columbus—I agree with the last speaker in always boiling my instruments wrapped in cotton, and on withdrawing the instrument wipe it with the cotton that was wrapped around it. I feel a degree of certainty that I could not feel in withdrawing an instrument from such a box as this.

Dr. ROBERT L. RANDOLPH of Baltimore—I think that we are under a slight misapprehension as to the exact action of heat. While wrapping the blades in cotton would undoubtedly protect them from mechanical injury, in the boiling process the high temperature would blunt the edge all the same. Dry heat will also dull the edge of the instrument in the same way. It has been shown that not only moist but dry heat, when of high degree, invariably impairs the keenness of a knife.

Dr. E. A. DE SCHWEINITZ of Washington—I might have said that 15 c.c. of formaldehyde solution should disinfect a small box like this for a week, no matter if it is opened three or four times a day, and consequently an instrument case might easily be kept clean all the time.

The amount of gas generated is about 1.5 per cent., and if the odor is strong when the door is opened one can be thoroughly satisfied that the instruments are sterile. In regard to the remark of Dr. Gifford about the method of testing, that might apply where the solution itself is used, but I do not think it applies to the gas. When the instruments are taken out one can not detect the slightest odor of gas, but rinsing them in boiling water would remove any particle of gas that might be adherent.

BEST METHODS OF PREPARING DRESSINGS FOR CATARACT CASES AND THEIR CHARACTER AND COMPOSITION.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY CASEY A. WOOD, M.D.
CHICAGO.

I must confess that I feel very much like dissenting from the proposition implied in the title given to

this communication, because I am in considerable doubt as to whether there is any *best* methods of preparing dressings for the average cataract case. My own experience and the results that I know others to have obtained teach me that when the patient has been prepared for operation and when the extraction has been deftly and completely accomplished, when the lips of the corneal wound have been carefully approximated and when no intra-ocular debris rests between the latter, when, in other words, the operation leaves nothing to be desired, the dressing is of little or no importance. In such a case it is of no moment whether the lids be simply closed with a strip or two of isinglass plaster or whether the eye be subjected to the elaborate toilet recommended by many distinguished writers and teachers. Indeed, in words which I have elsewhere used, as to the form that the dressing should take, we recognize today about the same difference of opinion that existed in the time of von Graefe and Beer: one school cries out for heavy bandages and absolute rest, the other for liberty and no dressing. One extremist applies to both ocular regions a thick flannel or gauze bandage over pads of borated gauze or even iodoform cotton, while other enthusiasts advocate a narrow strip of isinglass or other plaster, just large enough to keep the lids together. Doubtless each one of us considers his method the best, but even a superficial study of the course pursued by the healing process after cataract extraction will show that the great majority of cases do well with any kind of bandage or with none at all. If the operation be correctly done, it does not matter much whether or not the dressing be negatively aseptic or positively antiseptic. If, however, the operation fail in any important particular, the question may well arise as to what description of dressing is most likely to assist repair of the surgical traumatism, both by preventing extra-ocular infection and by favoring apposition of the margins of the wound. The first indication is probably best met by some covering for the eye that, while not entirely excluding ventilation, will yet be sufficient to prevent the entrance of morbid germs and irritating dust. It should also be sufficiently absorbant to take up the tears and mucus that commonly flow from an eye that has recently been operated upon. I have been unable to convince myself that a dressing impregnated with germicides of sufficient power to destroy any pathogenic organisms that have lodged in or about the eye does not do more harm than good. At any rate, the dressing is not the proper agent that should be depended upon to do the work of sterilizing the conjunctival sac, lids and lid edges. If this is attempted the hyperemia which the bactericide generally sets up is, at least positively harmful in the great majority of cases.

What good purpose is subserved by the attempt, so often made, to keep the corneal margins *in situ* by the use of bandages and other appliances? You are all well acquainted with these devices, the little rolls of cotton (aseptic and antiseptic), the simple roller, the starch bandages and other appliances of a similar nature. I have tried and discarded all of these, as I have found them entirely unnecessary in uncomplicated cases of extraction and never saw any good come from their employment even when in times of trouble, a mechanical support seemed desirable.

In my hands sufficient protection from external irritants, combined with an effective provision for the

absorption of post-operative discharges, may be secured by the following dressing, carefully sterilized and rolled in a sterilized towel until the moment of application. It is far from being original with me:

A layer of borated or plain absorbent cotton or wood wool two or three millimeters in thickness is applied to the surface of two single layers of sterilized gauze. These are together cut (so that they will adhere and form one piece) with a pair of scissors, in oval form and of a size to cover the orbital openings, reaching from the eyebrows to below the inferior orbital margin. Three pieces of adhesive plaster, each three or four inches long, keep this dressing in place and are so arranged that no portion of them presses upon the eyeball. This is accomplished by placing the first over the upper border of the pad, and firmly attaching it to the skin above the superciliary ridge; the second is carried parallel with the nose; the third completes the triangle. Such a dressing filters the air passing to the eye of its germs and dust; it is comfortable to the patient, does not unduly press upon the eyeball and readily absorbs lachrymal and other secretions. It does not, like the roller, starch and antiseptic bandage, encourage vascular congestion, and, finally, it may be impregnated or smeared with any agent that the surgeon cares to apply. Neither the patient nor his officious friend is at all likely to succeed in removing it, although the surgeon may examine and drop collyria into the eye readily.

What can be more provoking to the surgeon than to find, after obtaining a good operative result, that a careless nurse or a restless patient has added a newly opened corneal wound, a hernia of the iris or loss of vitreous to his other anxieties? A finger thrust, a pillow end jammed into the eye, a slight blow upon the globe or any other of the dozen little accidents that may happen to a person with imperfect vision moving about in darkened rooms, may nullify the most brilliant and correct efforts of the operator. Especially when night comes on, or when the patient begins to move about, should the eye be protected from injury by some sort of a shield or mask. Fuchs uses the wire-woven protector, introduced as long ago as 1883. There are many modifications of this mask in the market, one of the best of which has been suggested by Frothingham and Würdemann.

Certain operators who make use of the roller bandage gain protection by starching the dressing. When this has dried the eye will receive a considerable blow without injury.

Snellen has used a turtle-shaped aluminum shield, about ten centimeters long and five wide, placed over the eye and held in position with strips of adhesive plaster; it forms an admirable protector. One of the best shields I am acquainted with is the papier mache half-mask, which, when carefully adjusted to the nose and surrounding parts, makes a light, comfortable and effective protector. A small proportion of patients object to wearing any mask, complaining that it prevents them from sleeping and makes them nervous. In such cases I find that one may get along very well with a large, stiff and very concave eye shade placed over the dressing and held in place with a piece of rubber plaster.

DISCUSSION.

Dr. H. KNAPP of New York—I should like to begin with the paper of Dr. Wood because that is the beginning of the after-treatment. I think the object of the bandage is to immobilize the eye. We can fairly state that the prime factor in obtaining healing by first intention is rest. If that is obtained for the

eye an immense gain has been made. Among the bandages I think there is none so good as the old binocular. Dr. Wood mentioned it but gives preference to another kind of bandage, which I endorse and have used for about ten years. I usually use a pad of sterilized gauze, two or three layers, and this is put on moistened in a very weak solution of bichlorid. Upon that I place a pad of absorbent cotton, dipped in the solution also, and if you do that you can mold it exactly to the eye and secure a perfect splint. If it is applied dry it is impossible to put the plaster strips on because the cotton is resilient and does not hold it. It is easy to put one plaster strip over the nose, one over the brow and then a cross strip. This is all right where there is a sterile field and the operation has been perfect. It is convenient to the patient and can be removed readily. Nevertheless, we have a certain number of patients where the condition of asepsis has been thorough that are restless and continually move the eye during and after the operation, and there I think the binocular is better. I think too, when the patient can be relied upon not to toss very much it is the most comfortable bandage. Anything that becomes stiff is unpleasant. Professor Alt tried all the bandages upon himself and says that the most unpleasant is the isinglass strip placed upon the eyeball.

I think it is proper to look at the eye next morning, and in the case of a simple extraction it is essential, for there may be a prolapse and it is best to cut that at once, when you can make a clean iridectomy, and very little harm has been done by having attempted to operate upon a patient who was not fit for simple extraction. I open the eye next day, look at the edges of the lids and the conjunctiva first, and if a simple extraction I look also at the wound to see if there is anything the matter with it. Generally a prolapse indicates itself by pain, but there are some cases where the patient says that he has felt nothing. I do not think it is proper to leave the small prolapse to nature. It requires some after-treatment to help the healing forces of nature.

If there is no secretion I do not wash the eye at all, but if there is even the slightest amount I wash it with plain warm water and get the eyelashes free of any material that would be apt to decompose and by its irritating qualities produce more secretion of the conjunctiva. I use germicides as little as I can, scarcely putting anything into the sac, but when the lachrymal sac comes into play I am particular to have that cleansed carefully.

In regard to beginning suppuration of the flap, I have found the different methods used are more or less unreliable, and I have seen as many cases get well by the cautery as by other means. I think if we stick to simple methods we shall do better than by using too much treatment. We still lack simplicity, and we are not yet at the end of our search.

Dr. MYLES STANDISH of Boston—I would like to relate a case I operated upon some years ago, an old man with cataract in both eyes and with purulent discharge from each tear sac. He had been to the infirmary for a number of years and each surgeon had put him off with antiseptics for the tear sac, without ever stopping the discharge. The old gentleman finally came back and said he was resolved to risk an eye. He knew the chances of losing it, but he was taken into the house, the sac cleansed and the eye operated upon. After the extraction the lids were opened and iodoform in large amount was literally filled into the sac. The next morning the other eye had apparently a teaspoonful of pus, but the eye operated upon was dry. This treatment was continued and at the end of eight or nine days the bandage was removed and the iodoform discontinued, but at the end of twenty-four hours he had an infection of the entire edge of the wound. The actual cautery was used, iodoform was again begun and kept up for two weeks. No recurrence of the pus showed itself and the result was good.

Dr. J. C. DUNLAVY of Sioux City, Iowa—I wish to speak of the advice to leave the eye for four days without examining it. It appears to me that if for no other reason than the fear that iritis might occur, four days is entirely too long to let it go without observation. As to the treatment of prolapsed iris, the question of operating or letting it alone should depend very largely on the character of the prolapse. If in the form of a bead and you have reason to believe it will not be taken care of, naturally the sooner you cut it off the better, but if more or less flat, I believe nature will take care of many of those cases.

As to immobilizing the eye with a bandage, I know we have talked about it for many years, but having tried the bandages on my own eyes I am satisfied that it can not be done and the tighter you apply the bandage the more danger you will have when you have a patient that will not keep quiet. There is a certain number, as Dr. Knapp said, that will try to move the eye. In those cases, by a certain amount of education, you

can occasionally obtain better results by leaving the bandage more or less loose.

Dr. LEARTUS CONNOR of Detroit—In cases in which it is desired to cleanse the outside of the eye, or the eye itself, I have found a procedure which is a most efficient method. It is devoid of any possibility of injury to the eye. Hot water, as you all know, is an extremely efficient agent in many ways. A tumbler is taken, filled with water at as high a temperature as the patient can bear, the hotter the better; the tumbler is brought to a level in contact with the nose [demonstrating], and then tipped up as the head is brought forward, so that the eye is entirely immersed in the hot water. You may use an antiseptic solution if you please, but it is the method of making the application which I desire to place before you. You get the effect of moist heat without any mechanical disturbances of the relation of the eyelids to the eyeball.

Dr. ALBERT B. HALE of Chicago—I have used the method Dr. Wood has described. He mentioned some very nice experiments about immobilization. He says that if one eye only is protected there is a tendency to winking and the lid is not held so thoroughly as it ought to be; if both eyes are protected and the patient put into a dark room the tendency to winking is much reduced.

Dr. J. A. LIPPINCOTT of Pittsburg—I have been very much interested in the remarks in regard to immobilization and I suppose that when it is spoken of it is immobilization of the lids that is meant, for immobilization of the eyeball is impossible. Immobilization of the lids is possible by means of plaster, and while there may be some objection on the grounds of discomfort, I think this can be removed by the use of very thin and properly prepared plaster.

I was also interested in the statement that there is no way of sterilizing the plaster. I would like to show a box I got up some time ago for containing plaster [exhibiting box]. It is a small, circular, metal box with a split in the side of it, from which one end of the plaster can be drawn out. There is little movement allowed so that the cover slips slightly on the box and one can close the slit from which the plaster extends, almost absolutely. This box can be sterilized quite readily by putting it in a dry oven. All my experiments proved it to be sterile and I think that with the instrument shown by Dr. de Schweinitz it could be absolutely sterilized without injury to the plaster. It can not be used in the steam sterilizer. You draw out the plaster as you wish to use it and what remains in the box is in a reasonably good condition and does not require to be sterilized every time it is used.

Dr. F. C. HOTZ of Chicago—I wish to add my endorsement to the necessity for observing the first principles of surgery that wounded tissue should have as complete rest as we can secure to it if we wish natural healing to take place. This we can only obtain by binocular bandages so far as the eye is concerned. I still am an advocate of bandaging both eyes. It is the principle to observe and not the particular method. Another point I wish to mention is in regard to the pressure bandage. It was mentioned in one of the papers, that if anything happened to the wound a pressure bandage might be used to replace the prolapse. This is irrational treatment and if we take so much precaution to keep the eye protected from pressure I do not see why we should intentionally put pressure upon it.

Dr. S. L. ZIEGLER of Philadelphia—I have always used the lighter isinglass plaster dressing for cataract cases, by placing a strip across the upper lid and a cross-piece coming down on the cheek to hold the lid perfectly quiet, thus forming a T-shaped splint. As soon as desired we can remove the vertical cross-piece. The strip on the upper lid will sufficiently immobilize the eye and at the same time allow the eye to be opened wide enough to wash it. In addition to this a light dressing is applied consisting of a piece of gauze with a little cotton laid over the margin of the lower lid to catch the moisture (aqueous blood and tears), and over this the black Liebreich patch. The unprotected eye is also immobilized in the same way. This dressing seems to me to answer every purpose and is sufficiently cool to avoid conjunctivitis. All dressings are removed on the fourth day.

Dr. DUDLEY S. REYNOLDS of Louisville—I wish to emphasize the necessity for securely fixing the unoperated eye and I think the lightest possible dressing constitutes the most desirable form. I am in the habit of varying the dressing in accordance with the prominence of the brow and cheek. A protruding eye is more readily pressed upon by dressings placed over it than a receding one. I am an advocate of quiet for the wounded eye and of non-interference with it so long as it manifests no sign of trouble, but the dressing should be of such a character as to enable the surgeon to remove the dressing on the slightest indication of trouble.

Dr. J. A. WHITE of Richmond—In a paper of ten minutes it is impossible to go into details that are necessary to put yourself entirely right and therefore criticism is made because you are not understood. Someone stated that it was strange that I did not look at the eye before the fourth day. I did not say that; I said I did not examine the eye unless necessity called for it. I rarely take off the bandage before the third, sometimes on the second day. One of the most distinguished ophthalmologists in America wrote me that he did not look at the eye for eight days, and that is the result of his forty years' practice. I was astonished at it, as you will be.

In regard to prolapse, I have simply stopped operating upon it unless I know that it is there immediately after the operation, because the cases I have lost are the ones that I meddled with and the ones I let alone usually get along very well. Until I find that method giving me worse results than the other I shall still let them alone.

Dr. C. A. WOOD of Chicago—There is some confusion in referring to the immobilization of two different structures, the lids and the eyeball. The reason why I said it was difficult to understand the rationale of bandages pressing upon the eyeball is that the pressure is made there upon the anterior segment. When the eye is closed it is the equatorial region we have to deal with and such a pressure is likely to do harm because it is distributed over the wounded part of the eye and brings about the very condition we wish to avoid. As to immobilization of the lids I think I have gained as good results by impressing upon the patient the absolute necessity of keeping the eye closed and by speaking about it two or three times a day. I have obtained as good results in this way as by attempting to keep it closed by bandages.

I am glad Dr. Lippincott has been able to sterilize the plaster. I undertook a number of such experiments and found that when one succeeded in accomplishing disinfection, the plaster was so affected that it was useless.

ASTIGMATISM FOLLOWING CATARACT OPERATIONS AND OTHER CORNEAL SECTIONS.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD JACKSON, A.M., M.D.

Professor of Diseases of the Eye in the Philadelphia Polyclinic; Surgeon to Wills' Eye Hospital. PHILADELPHIA, PA.

The brief observations here presented are to be regarded as addenda to the paper on the subject read by the author before the Pan-American Medical Congress in 1893.

Probably in every case of cataract extraction the necessary corneal section is followed by a permanent change in the corneal curvature and refraction. In a few cases the change in curvature is such as to reduce or correct, or slightly over-correct, a previously existing asymmetry of the cornea, and the astigmatism caused by it. In the larger proportion of cases the ultimate effect is a considerable astigmatism, greater in amount and essentially different in direction from any astigmatism that may have been present before the operation.

The fact that the astigmatism is new, and also that it is due to change in the corneal curves, give it increased importance. Those who always have had astigmatism never perceive the distortion of retinal images that it causes. Those who acquire astigmatism slowly may feel some disturbance on account of such distortion, but are not distinctly conscious of its effect. Those who have astigmatism corrected in early life quickly become accustomed to the greater distortion of the retinal image caused by correcting lenses. But cataract extraction is usually done at an age when acquired astigmatism is always found very annoying, when the full correction of astigmatism, congenital or long present, is sometimes not practica-

ble, and astigmatism after cataract extraction comes on suddenly, always causing marked distortion of the retinal images. Hence, it is certain to cause annoyance; and its correction is generally a real service and one which is appreciated.

Post-operative astigmatism necessarily follows such a corneal section, although it is not necessarily always permanent. The form of the cornea depends on the intra-ocular pressure and the relative resistance of different parts of the corneo-scleral coat. Only when intra-ocular pressure is entirely removed, as it is by the escape of the aqueous humor through the corneal section, can the cornea take a form determined entirely by its own structure. This does not usually differ from that which it had before the operation. When the healing of the corneal wound becomes sufficiently advanced to cause the retention of aqueous humor, the intra-ocular pressure begins to rise and gradually increases until it reaches the normal.

If the resistance of the sclero-corneal coat were entirely uniform throughout its whole surface, the intra-ocular pressure would cause the eyeball to assume the shape of a perfect sphere. The departure from this perfectly spherical shape is determined by the difference of resistance of intra-ocular pressure by different parts of that coat. Thus, the reinforcement of the cornea and sclera in the neighborhood of the sclero-corneal junction by the ring of tissue constituting the ciliary body, strengthens the coat at this point so that it resists the intra-ocular pressure and causes a depression, making the corneal surface the part of a smaller sphere set into the side of the larger sphere of the sclera.

After corneal section, the cornea at the line of incision is weakened as compared with the remainder of the sclero-corneal coat and correspondingly gives way or bulges. Its bulging at this point necessarily causes an equivalent flattening in other parts of the same meridian. The extent of this bulging and distortion is proportioned to the relative weakness of this line of corneal tissue. Hence, when the cicatrix is weakest, the bulging and distortion and consequent astigmatism are greatest.

Generally the first measurement after cataract extraction shows the highest astigmatism; but not unless the wound has become thoroughly closed and the tension of the eye restored to normal. Thus, in a recent case on the fourteenth day after extraction, the astigmatism was found to be only 2 D. But a week later it had risen to 10.5 D. After this it gradually declined in the usual manner. At the first measurement the anterior chamber had been re-established for some days, and it was not noted that the tension of the eye was below normal. Yet the subsequent change of astigmatism can only be accounted for on the supposition that at the first observation the ocular tension was still lower than at the time of subsequent observations. With this exception the cases that I have watched have shown the highest astigmatism at the first examination; and only very few have shown a slight temporary increase of astigmatism at any time afterward.

The highest post-operative astigmatism I have yet encountered was 26 D. in one of the cases mentioned in my former paper. The case was one of simple extraction and of normal healing. In two and one-half months the astigmatism had fallen to 0.75 D.

The amount of astigmatism that remains permanently is always very much less than that discovered

at the first testing, two or three weeks after a cataract extraction. While this is often 10 D. or upward, the final amount is very rarely over 3 D. In one patient I have seen it 4.5 D. in the right eye and 5 D. in the left, three and a half years after the cataract extraction. But in no other case have I seen it remain as high as 4 D.

The practical application of this fact is that where one is compelled to prescribe glasses within a few weeks after extraction, which glasses will be worn by the patient when out of the reach of anyone who can properly measure refraction, it is better, however high the astigmatism may be at the time, to give a cylinder of not over 3 D. This will almost certainly in a few weeks be nearer the proper correction than the lens indicated soon after operation. In prescribing such glasses it is also important to make the spherical somewhat stronger than is at first required, because it is equally certain that after the first few weeks there will be found an increase of hyperopia as well as a decrease of astigmatism.

All observers have noticed that in post-operative astigmatism the cornea is flattened in the meridian at right angles to a straight line joining the ends of the corneal wound. An incarceration of the iris, or irregularity of healing due to other causes, may occasion a slight variation in the meridians of astigmatism, but such variations in direction are slight. In many cases no change occurs in the direction of the principal meridians during the weeks or months through which the astigmatism continues to diminish.

In regard to the influence of different forms of cataract operations, on the amount or course of the astigmatism, I am still unable to recognize any decided influence from the position of the corneal section. This seems rather strange. One would be inclined, *a priori*, to expect the greater astigmatism when the corneal section was situated near the area of the cornea through which the rays had to pass, or from which the reflections of the ophthalmometer were to be obtained. It is possible, however, that the depression at the sclero-corneal junction permits from the same incision a greater distortion of the cornea when the incision is situated at the periphery; and that thus it serves to balance the effect of proximity of sections placed nearer to the center of the cornea.

CATARACT STATISTICS WITH COMMENTS.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY HERMAN KNAPP, M.D.

NEW YORK, N. Y.

Statistics of cataract operations can be made from different points of view. It is plain that complicated cases do not give as favorable results as uncomplicated ones, and therefore almost all statistics refer only to uncomplicated cataracts. Yet this does not make them comparable with one another, for Dr. A. will count cases among the complicated which Dr. B. will consider uncomplicated. To present a faithful picture of what an operator has accomplished, all his operations should be counted, or if he excludes some he should supplement his statistics by a special report, best with abstracts of the cases.

Another point in which reports differ is the standard of success and failure. Shall we make success dependent on the acuteness of sight, or on the perfection of the recovery? Sometimes we have to extract

lenses from incurably blind eyes, say a chalky, partially or totally dislocated lens in a young person, the eye being otherwise in good shape and its fellow normal. If we succeed in getting that cataract out without mutilating the eye, we do not only improve our patient's appearance, but his chances for the preservation and quiescence of the eyeball. To accomplish this requires greater skill than most other cataract operations, and the surgeon is entitled to put such a case to his credit. Let him call it an "operative success." It is questionable, however, to classify under this heading extractions that have been followed by a smooth recovery, but will yet require an after-operation to clear the pupil from remnants in order to restore sight. However probable the good result of such an operation may be, we are not justified in counting those cases among the perfect results until their vision is perfect. I find, for instance, in a very excellent report as to accuracy and completeness of the records of all cases of extraction¹, the summing up of the second series of 100 cases as follows: "Full success in ninety-seven cases. Visual acuteness from 5-5 to 5-30 in seventy-two. In twelve cases V. was not tested, the recovery not yet being complete, or secondary cataract being present; but in all, the convalescence had so far advanced that a good result could confidently be expected."

The following remarks are based on an analysis of the last 1,000 extractions I have made:

Intercurrent with the first 600 consecutive cases there were thirty which I checked off because they had complications so grave as to render the restoration of useful vision improbable. I have made use of this series on a previous occasion, for the discussion of special points connected with the great question of cataract extraction². The series of the 400 consecutive cases comprises all extractions, without an exception, that I operated on from Sept. 19, 1894, to May 17, 1897.

Reserving a detailed communication for the *Arch. of Ophthalmology*, I beg to present for your consideration and discussion the following topics:

1. *Complicated cataracts, their nature and treatment, with final results.*—Among the 400 cases fifty-seven, that is 14.25 per cent., showed the one or other complication, namely: 1. Diabetes, six cases; five smooth, one protracted recovery. This agrees with my previous experience that diabetes has not so bad an influence on the recovery from cataract operations as is stated by some authors. 2. Albuminuria, two cases; good recoveries. 3. Diabetes and albuminuria, two cases; good recoveries, the one had retinal hemorrhages which two years later had disappeared with S. 20/20. 4. Gout, one case; healing slow, result good. 5. Rheumatism, one case; good. 6. Insanity, three cases; two failures by suppuration, one good visual result, but patient on the day of discharge committed suicide. 7. Chronic bronchitis, cough, two cases; one good, the other perception light (partial suppuration). 8. Traumatism, three cases; good. 9. Foreign body in lens (came out with cataract), one case; good. 10. Chronic dacryocystitis, six cases; three good, three failures by suppuration. 11. Excessive myopia, four cases; good, but one had sudden detachment of the retina seven months after discission. 12. Synchysis, three cases; good. Diagnosed by copious escape of watery fluid

during the section, cataracts expelled by external manipulation. 13. Choroditis, disseminate and atrophic, three cases; recoveries smooth. 14. Chronic iridochoroiditis, eight cases; seven yielded satisfactory results from V. 4/200 to 20/70, one was a failure by closure of pupil after cysto-iridectomy. 15. Maculæ cornæ, four cases; good. 16. Chronic glaucoma, three cases; recoveries smooth. 17. Optic nerve atrophy, two cases; recoveries good. 18. Nystagmus, congenital, one case; good. 19. Chalky lens, dislocated into anterior chamber, one case; good operative success. Lens expelled by external manipulation with permanently round pupil. 20. Previous syphilis, one case; good. There were eight failures among the fifty-seven cases of complicated cataract, *i. e.*, 14 per cent. Of the cases of dacryocystitis 50 per cent. were lost.

2. *Extractions with iridectomy, their indications and visual results.*—The conditions which determined me to make an iridectomy during or prior to the extraction in the last 400 cases were as follows: 1. Tendency to iris prolapse, nine cases; 2, glaucoma, preliminary iridectomy, two; 3, diabetic retinitis, preliminary, one; 4, albuminuria, preliminary, one; 5, patient demented, one; 6, profuse hemorrhage in anterior chamber, two; 7, patient unmanageable, eight; 8, iris fell over knife, five; 9, rigidity of sphincter iridis, one; 10, loss of vitreous, one; 11, no reason stated; *a.* preliminary two, *b.* simultaneous three, five; 12, peripheral section, two; 13, synchysis, rupture of suspensory ligament, lens tremulous or dislocated, nine; 14, iritis, iridocystitis, iridochoroiditis, five; 15, corneal section insufficient, iris bruised, one; 16, splinter of wood in lens, one; 17, to remove thickened capsules, one; total, fifty-five cases, *i. e.*, 13.75 per cent. were combined with iridectomy.

On these fifty-five cases fifteen *secondary operations* were made, namely: Discission, eleven; extraction of capsule, two; iridectomy for consecutive glaucoma, one; cyst-iridectomy, one.

The final visual results were as follows: *Good*, *i. e.*, S. 20/200 to 20/20 in forty-two cases; *moderate* (S. 2/200 to 18/200), six cases, namely, from cataract accreta one, glaucoma chronicum two, retinitis diabetica one, synchysis one, no cause noted one; *failure* seven cases, viz., iridocyclitis six, tendency to prolapse and chronic conjunctivitis one.

3. *The reactive processes* may be divided in two groups:

A. Inflammatory.—1. Mild iritis, six cases; five with good, one with moderate (S. 10/200, complicated, good operative recovery) vision. There was a moderate number of non-irritative filiform synechiæ, simple agglutinations of the torn pupillary border of the iris to the shreds of the incised or lacerated capsule. These had no influence on the visual result and did not thicken the center of the capsule. 2. Protracted iridocyclitis, two cases; *a.* angular incarceration with temporary + T. pilocarpin, S. = 1/200; *b.* iris wounded with knife; abscised. Remnants laboriously pressed out 1- α . 3. After-hemorrhage into anterior chamber, 20/40. 4. Slow closure of wound; patient aged 83 years; kept in bed; on eleventh day pneumonia and pleuritic effusion. Complete recovery. Discharged thirtieth day: V. = 20/40. 5. Partial purulent wound infection, two cases; *a.* slight hypopyon. Recovery 20/200, vitreous still turbid. *b.* Old iritis, iridectomy twenty-two years previously. Difficulty in delivering lens (cat. nigra). Anterior chamber opened daily 1- α . Cornea clearing. 6. Total suppuration, four cases; all from wound in-

¹ F. Zenker: Report of 1,000 cataract extractions made by H. R. H., the Duke, Dr. Carl in Bavaria, Wiesbaden, Bergmann, 1895.

² See Transactions of the Eighth International Ophthalmological Congress, Edinburgh, 1894, p. 14, etc.

fection in laborious operations. In three the infection was primary, in one secondary by exposure on the fifth day; remained partial until the fourteenth day. S.=0, in all.

B. Mechanical.—1. Anterior synechiæ. A goodly number of small adhesions to the scar was noticed with distorted pupil, but good sight and no irritation. One case was severe; broad, traumatic adhesions on sixth day, slowly developing glaucoma. Patient having good sight, left hospital secretly, returned in twenty-five days with pronounced glaucoma, Tn.+2, anterior chamber totally obliterated, iris and lens touching cornea. Fingers 1'. Iridectomy with Graefe's knife. Escape of vitreous as usual in such cases. Eye immediately free from pain and irritation, anterior chamber filled again, Tn., fingers at 3'. 2. Prolapse of iris twenty-six cases, *i. e.*, among 343 simple extractions, =7.6 per cent. It occurred mostly in the first night, frequently on the second or third day, rarely later. The eyes were inspected daily and the prolapse abscised at once; cocain anesthesia was sufficient; in two, general anesthesia was administered. The latter should always be resorted to if the patient is nervous or refractory. The recovery and vision were good in all cases but one, where from chronic cough, prolapse occurred on third day. The prolapse was abscised but partial suppuration set in; S.1/ α . Good projection.

4. *Secondary operations.*—The 400 extractions were succeeded by 160 after-operations, *i. e.*, 40 per cent. They were: 1. Enucleation, one case, viz., traumatic dislocation of lens into the anterior chamber; extraction leaving capsule in did not relieve the glaucomatous iridochoroiditis. 2. Iridectomy in one case of glaucoma following extraction, raised 1/200 to 3/200; good operative result. It might have been a good visual result had the patient not withdrawn from treatment for two months. 3. Iridectomy in three cases of glaucoma following discission; immediate relief, rapid recovery and good sight in all. One case of acute glaucoma occurring on the fourth day after the discission, was cured by eserine and subcutaneous injections of morphia. 4. Extraction of thickened capsule, after discission with one and two needles had failed, two cases; results good. 5. Discission 153 cases, *i. e.*, 38 per cent. The visual improvement was very considerable. The ultimate visual acuteness in the 139 uncomplicated cases was: 20/20 in nineteen; 20/30 in forty-three; 20/40 in thirty-two; 20/50 in seventeen; 20/70 in thirteen; 20/100 in ten; 20/200 in five. It had deteriorated the sight in no case; it left the sight as it was in two cases; it was followed by acute glaucoma in four cases (1 per cent.), which by eserine in one and iridectomy in the three other cases, was cured with the ultimate vision better than the primary. In one case the discission was successfully repeated two months later, the opening of the capsule having partially contracted.

One of the cases of glaucoma assumed a most serious aspect. Under the picture of cyclitis hypopyon developed, for which no source of infection could be discovered. The iris began to bulge and the eyeball-tension rose to Tn.+1. The pupil remained open. An iridectomy put an immediate stop to all the symptoms. Pain, bulging of iris, and + Tn. disappeared, the vitreous cleared up and the patient regained excellent sight. The whitish sediment at the bottom of the anterior chamber can not have been purulent, *i. e.*, real, infective, hypopyon, but merely puriform, *i. e.*, bland, such as we find it on introducing aseptic irri-

tant substances into the anterior chamber. The other cases showed no alarming symptoms, most of them no reaction at all.

5. The visual results of the last 400 cases was as follows: From 20/200 to 20/20, 359 cases, *i. e.*, 90 per cent. good results; from 1/200 to 18/200 twenty-nine cases, *i. e.*, 7 per cent. moderate results; from 0 to 1/ α (perception of light) twelve cases, *i. e.*, 3 per cent. failures. Full vision, 20/20 was obtained in twenty-three cases, 6 per cent.; almost full vision (20/30) in seventy-one cases, 18 per cent.; vision good enough for all purposes (20/40) in sixty-seven cases, 17 per cent.; 20/50 in sixty-four cases, 16 per cent. The visual results of the preceding 600 cases (not before published) were as follows: 20/20, 106 cases; 20/30, 156; 20/40, ninety-three; 20/50, sixty-three, etc. V. from 20/200 to 20/20, 572 cases, = 95 per cent., good; V. from 1/200 to 15/200, sixteen cases, = 3 per cent., moderate; 0 and 1/ α twelve cases, = 2 per cent., failures. The results in that series are somewhat better, but it has to be remembered that thirty cases intercurrent with and additional to the 600, have been omitted as offering too poor a prognosis. Thirty cases out of 600 is only 5 per cent., which should be borne in mind when these statistics are compared with others that rest on a different basis. Adding the results of the two series, *i. e.*, a series of 1,000 successive cases, we obtain according to the conventional calculation: Good vision in 93.1 per cent.; moderate in 4.5 per cent.; failure in 2.4 per cent.

Combining as above the results of the two series, we obtain the following data on points also discussed in this paper. Of the 600 extractions of the first series fifty-two, *i. e.*, 8.6 per cent³, were combined with iridectomy: of the 400 extractions of the second series fifty-seven, *i. e.*, 14.25 per cent., which makes 52+57=109 iridectomies in 1,000 extractions, *i. e.*, 10.9 per cent. Prolapse of the iris occurred in fifty-five cases of the first series, *i. e.*, fifty-five in 548 cases of simple extraction, which represents 10.3 per cent. In the second series there were twenty-six cases of iris prolapse among 342 simple extractions, *i. e.*, 7.6 per cent. In the two series there were eighty-one cases of prolapse of the iris in 891 simple extractions or 9.1 per cent. In 300 cases of simple extraction published by me before (*Arch. of Ophth.*, 1888, '89, '90) there were in three separate series severally 8 per cent., 6 per cent. and 12 per cent. of prolapse. In an extended series of cases every complication occurs. At the Eighth International Ophthalmological Congress (l. c. p. 17) I summed up the results of the fifty-five cases of prolapse which happened in the 600 cases under consideration: Forty-nine had good vision, two had moderately good vision, two lost the sight in the eye operated on, and two lost the sight in both eyes, in the non-operated eyes by sympathetic ophthalmia. The latter appalling calamity is fortunately rare and occurs where the iris is wounded, in the combined extraction oftener than in the simple. Secondary operations were performed in 66 per cent. of the first series, in 40 per cent. of the second. They were discissions in almost all cases and will sum up higher in the latter series, when more time has elapsed for patients to return.

DISCUSSION.

Dr. G. E. de SCHWEINITZ of Philadelphia—I am in hearty accord with the suggestion that cases of cataract presenting marked complications should be recorded separately. The

³ See Trans. Eighth Internat. Ophth. Congress, Edinburgh, 1894.

operator is certainly entitled to the credit of an "operative success," even if the visual acuity does not reach that standard which we call a success, provided the nature of the case was such that it precluded the possibility of the restoration of a visual acuity amounting to one-tenth. In the Philadelphia Hospital I operate on many complicated cases—insane patients, cases with chronic conjunctivitis, chronic bronchitis and cases with advanced general diseases, for example widespread arteriosclerosis, diabetes, etc. Some of my results have been surprisingly good; others have been poor, although in all my experience in this hospital I have only once had a suppuration, and that was localized. In another hospital I have had two general suppurations and lost the eyes, one occurring after extreme prolapse of the vitreous, the patient at one time having had sugar in the urine, and the other in a patient who had chronic conjunctivitis and seborrhea of the face. In patients with chronic bronchitis I prefer the combined operations. Insane patients are usually satisfactory; occasionally I have been obliged to use a form of straight-jacket after the operation. It would be instructive to compile a statistical table of the usual results in cataract patients at long periods, one or even years, after operations.

Dr. S. M. BURNETT of Washington—My own experience has been that astigmatism immediately following cataract extraction is sometimes very enormous; that is, that at the end of two weeks there may be an astigmatism ranging as high as 8 D. It is evident that the visual acuteness does not then represent to the surgeon's credit what it should. The cornea does not settle down to the normal curvature under three months after the operation; I have noticed a gradual change for the better up to that time. So in registering the acuteness of vision some idea of the time of taking it should be taken into consideration before we can accept them as definite results. Usually the longer the time after the operation the examination is made, the more to the credit of the surgeon will it be.

Dr. H. B. YOUNG of Burlington, Iowa—These remarks remind me of an experience I had some time ago with a patient who had glaucoma in one eye and cataract in the other, which was operated on. At the end of six weeks the vision was so poor that I thought it a failure. The Javal ophthalmometer showed an astigmatism of 8 D. With proper correction she could read any type on the page. Four months later she had the same good vision with a correction of six diopters.

Dr. L. WEBSTER FOX of Philadelphia—At present each man is a law unto himself as to the relative results he gets. Some fixed law should be established, and I think we could do no better than follow Dr. Knapp, whose experience is second to none in this country and equal to many of those abroad. Of course we all try to arrive at J. 1. and 20-20, but we are frequently disappointed. Our results may be brilliant at the time of operation, but through some change brought about by senile changes in the individual they fail. Quite a number of cases recur to me, in which after a severe winter the patient has come back complaining of failing vision. I remember in one case with a very brilliant result, 20-20 and J. 1., the vision has fallen to 20-70 and I can find no cause for it. He is eight years older than he was when operated on, and I think there is a sympathetic condition growing with his senility.

Dr. F. C. HOTZ of Chicago—It seems to me, if I understood Dr. Knapp right, that in his method of registering cases he introduces a new meaning to the term complicated cataract that might lead to confusion. Under this term so far is understood complications in the eye, but what Dr. Knapp calls complications includes syphilis, bronchitis and other diseases, and thus the number of complicated cataracts would outnumber the uncomplicated ones.

Dr. DUDLEY S. REYNOLDS of Louisville—I hardly think it is fair to classify those ultimate results found in aged people as having at all to do with the operation. We all know how prone old people are to changes in the choroid and retina, and it is hardly fair to pick out the case of a man who has had good vision for three or four years and put down changes in the optic nerve or choroid as having any relations to a past cataract operation.

Dr. G. E. DE SCHWEINITZ of Philadelphia—I do not think that was implied. The case was only mentioned as being an interesting observation.

Dr. FRANK ALLPORT of Chicago—I wish to add one instance to the case given by Dr. Knapp as occurring in people with mental infirmities. I have had one similar experience, an old man whom I operated on for cataract with apparently good results. After eight or ten days, the nurse having left him for a minute to go to the linen closet, the patient jumped out of bed, threw himself out of the window and was killed. It may be interesting to state the case as showing the amount of care we must give such patients.

Dr. S. D. RISLEY of Philadelphia—I am very much pleased to see that Dr. Knapp has included the cases suffering from general dyscrasia among the complications of cataract. I am sure this ought to be considered in a large number of cataract cases before giving our prognosis. I have been for many years insisting that cataract is, in a large number of cases, a complication of some general disease. The difficulty is where we shall draw the line with diabetes, gout, rheumatism and syphilis. A large number of old people are gouty or rheumatic, and have changes going on that might produce cataract. I am glad to see attention drawn by so eminent authority to their harmful influence on healing after an operation. Surgical delirium is one of the not infrequent sequelae. I have had three examples within the past year. I remember that a few years ago one of my colleagues had a patient who jumped out of the window at the hospital a few days after the extraction of cataract, in a fit of surgical delirium.

Dr. G. C. SAVAGE of Nashville—Speaking on the point of insanity none of us would operate on patients who were insane at the time of operation. I have had two cases in which insanity followed the operation and it was clearly due to the use of atropin. Of course this occurs in patients peculiarly susceptible to the drug. I discontinued the use of it and the result was good.

Dr. HAROLD GIFFORD of Omaha—The question of how much more we should exercise in keeping these patients from jumping out of windows, etc., is important. I have had one or two cases and it seems to me that where it is possible we should have the patient watched all the time, at least until the first night or two is passed. A device that is not original with me, but which is worth trying, is to tie the hands loosely but so they can not get them up to pull at the bandage. The patient could be instructed as to what to expect, and it gives no discomfort and may prevent injury. The question is how much of this delirium results from the excitement and fear that occurs when these old people awake suddenly and find that they are absolutely blind; particularly if they have had one good eye. In some of these people, while I believe most firmly in closing both eyes ordinarily, I have left their good eye open so that if they should wake up and have a tendency to be scared they can reassure themselves by the use of this eye.

Dr. C. W. KOLLOCK of Charleston, S. C.—One class of patients has not been mentioned. It includes those patients that have false images before the removal of the cataract. I had a patient who saw all sorts of images at night, and the family thought she was losing her mind. After the operation these images disappeared and she was not troubled again until the last few months, when thickening of the capsule began to appear and she is now seeing them again.

Dr. J. A. LIPPINCOTT of Pittsburg—Some years ago I introduced a table with such a report to explain the cases where vision is below 20-40. It might be enlarged to include all cases below 20-20. On one side of the table was 20-40, 20-60, etc., down to nothing, and then running along the upper side of the table were the causes for the deficient vision, atrophy, detachment, opacity of the capsule, etc. A table like that can be added, or something of that kind should be appended to one's report so as to give at a glance an explanation of all the cases.

Dr. HERMAN KNAPP of New York—Dr. Hotz was perfectly correct in saying that constitutional troubles ought not to be put into the statistics of complications. It is the ocular complications that are ordinarily reported. In the last 400 cases I wanted to go over the whole subject, however, and mentioned all the factors of the system that could influence my judgment or determine my action as to the operation, after treatment and results. Complications like diabetes would weigh very little because we now think they do not seriously prevent good results. As to the point made by our president, as to the time statistics should be taken, that is an exceedingly important feature, but it is difficult to ascertain statistics after any length of time. There are between forty and fifty of my cases where only the primary results, when the patient was discharged two or four weeks after the operation are noted. When they turn out badly I get to see them again, but when they remain good there is no cause for them to come; so if we make up our statistics with the results that are attainable that is all we can do. It might be well to state the primary vision and the ultimate vision, for it would complicate our tables very little.

As to cases of deterioration I want to ask whether an operation on the capsule had been done in the case mentioned by Dr. FOX. Dr. FOX—Yes, sir.

Dr. KNAPP—I have found that where the capsule is not divided after the operation, at some time or other it is apt to block the vision. I can mention a case that Swanzy had operated on and the patient could read well for years, but gradually her vision was becoming dimmer and dimmer, and was only 10-200 when she came to see me. The whole fault was

nothing but a clouding of the capsule and when I made a division of it she was restored to good sight. That prompted me to make secondary operations in as many cases as I could get hold of. After this capsulotomy there is one objectionable feature that I would like to eliminate, that is the occurrence of glaucoma. It is sometimes acute and comes on within a few days after the operation. Then it is almost always cured. It occurs in about 1 per cent. of all the cases, which is a great deal. In a few cases it is cured by eserine. Glaucoma may occur in such cases any time after the operation. I saw it once in a case of Dr. Agnew after thirty years.

A REPORT OF THIRTY CASES OF CATARACT EXTRACTION WITH REFERENCE TO THE TREATMENT OF PROLAPSE OF IRIS FOLLOWING SIMPLE EXTRACTION.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS F. LOVE, M.D.

OPHTHALMIC SURGEON TO ST. MARY'S HOSPITAL, ETC.
PHILADELPHIA.

Undoubtedly the ideal method of cataract extraction is that in which the lens is removed without iridectomy. But in view of the much better results obtainable by the average operator with iridectomy I am inclined to think that simple extraction should be reserved for selected cases. Certainly it is safe to say that young operators should always use the combined method and wait until their judgment and skill are considerable before attempting simple extraction. The adoption of strict asepsis and antisepsis by the modern ophthalmic surgeon has, no doubt, made simple extraction of cataract more popular at the present day; but the great drawback still remains in the liability of prolapse of the iris coming on after the operation. On my return from Europe two years ago I determined to adopt simple extraction. Twenty out of thirty cataract cases were consecutively operated upon without iridectomy, and in four of them prolapse of the iris ensued in one or more days. This was a large percentage, but even the most skillful surgeons, acknowledge 6 to 9 per cent. It is evident then, that the most careful operator must often face the problem of iris prolapse and the important question arises how best to deal with this very likely complication.

Desiring to ascertain the procedures employed by various prominent surgeons in this country and in Europe, I wrote to a number of them. Among the answers were letters from Dr. de Schweinitz and the late Dr. Keyser of this city, Dr. Knapp and Dr. Noyes of New York, Dr. Fuchs of Vienna and Dr. Trosseau and Dr. de Wecker of Paris, some of whom I will quote, and afterward I will describe my own method somewhat in detail.

Dr. Knapp kindly wrote as follows: "For the last several years I have, or rather Dr. R. O'Born as my associate at the New York Ophthalmic and Aural Institute, has been in the habit of inspecting each eye within twenty-four hours after an extraction, be there symptoms of reaction or not. If there is iris prolapse I cut it at once, reduce the edge of the coloboma and obtain, in almost every case, as undisturbed a recovery as if I had made an iridectomy before or during the extraction. Formerly I inspected eyes the first time, three days after extraction if the patient felt comfortable, and abscised prolapse, if at all, rarely before the tenth day. This gave rise to high

degrees of astigmatism on the one hand and to an impure artificial pupil on the other. I mean irregular incarceration of the edges of the coloboma. During the last years I have made simple extraction in relatively more cases than ever before. Prolapse of iris has been very rare, and when it occurred the immediate abscission converted the case into one of combined extraction. I make the abscission in manageable patients under cocaine and in nervous and unruly patients under ether."

Dr. Noyes is in the habit of doing an iridectomy as early as possible unless the prolapse is very small.

Dr. de Schweinitz usually follows the rules laid down by Dr. Knapp, whom he quotes: "If the prolapse is discovered within a few hours after its occurrence it is cut off and the edges of the iris reduced exactly as after the operation of iridectomy. If the prolapse is not noted until the third or fourth day it is allowed to remain. Small prolapses may disappear, others produce no irritation, while still others become larger, constricted at their bases or cystoid. These are allowed to remain until the irritation has disappeared and then they are amputated in the same manner as a small staphyloma is abscised." "In a few cases in which there has been some gaping of the wound after the amputation I have inserted a delicate silk suture."

The following is a translation of Dr. Fuchs' letter: "If in the days following the extraction prolapse of the iris occurs I not only cut the iris off, but I cut it out; that is, I draw it a little forward, carry it away with the scissors and go then with the Daviel spoon in both corners of the wound in order to place back the coloboma. I consider the thing ended only when both of the sphincter columns stand equally deep and a regular coloboma exists as if an iridectomy had been done. It is true that this does not succeed perfectly in all cases, as for example, when the patient squeezes the eyelids too much and thereby the vitreous threatens to come out. In cases where subsequent excision of the iris has been done I have seen only one case of iridocyclitis. Otherwise the cases have gone along very nicely. I commenced the simple extraction only two years ago and I still operate on more than half the cases with iridectomy. For this reason I have up to this date only 725 simple extractions to show with about 6 per cent. with prolapse. This would therefore give about forty cases of subsequent excision. Those cases where the iris only late (*i. e.*, after the first eight days) and by degrees pressed itself to the wound, and which in these cases is usually very small, I generally leave untouched."

Drs. Oliver and Risley cut off the prolapse if it is discovered within forty-eight hours, otherwise it is allowed to remain.

In my own cases I have always cut off the prolapse as soon as it is discovered, which fortunately has always been within forty-eight hours. I have also been extremely careful to thoroughly cocaineize the eye and to use strict asepsis in every detail, and antisepsis as well, where indicated. In removing the prolapse I used no speculum, but had my assistant employ a retractor and, if needed, the fixation forceps, to pull down the globe. This is somewhat unhandy for the operator, but much safer for the eye. I think that prolapse of the iris could often be avoided if greater care were exercised in the expulsion of cortical matter, clear cortical masses being especially dangerous.

The preliminary preparation of cataract extraction consisted of having them under control for about two or three days before operation. The whole body, including the scalp, was bathed in warm water and soap bath, the nasal passages carefully washed out two or three times daily with an antiseptic wash and the conjunctival sac flooded three times a day with a saturated solution of boric acid. A purge was given the day before operation.

Name.	Age.	Diagnosis.	Condition.	Operation.	Visual result.	Remarks.

All instruments except the Graefe knife were sterilized in soda solution. The Graefe knife was dipped in a boiling soda solution and, along with the other instruments, put in absolute alcohol and all carefully wiped with sterilized gauze. The solutions of cocain and boric acid were rendered sterile as far as practi-

cable. Cocain (2 per cent.) was always instilled into the eye about twenty minutes before operating (and repeated), as this seemed to produce anesthesia of the iris, preventing the patient from squeezing the lids during the delivery of lens or during iridectomy. At the time of the operation the patient's face was thoroughly washed with warm water and soap, followed by bichlorid, 1 to 2,000. The eye was washed out with a 1 to 5,000 solution, and just before the incision a 1 to 2,000 solution was dropped over the globe, which I believe is the custom of Dr. Knapp. My hands and those of the assistants were carefully looked to. Lately I have used sterilized gloves as employed by Landolt. These are put on immediately after washing the hands in the bichlorid solution and are not removed until the time of the operation.

A very light aseptic gauze bandage with pads (dry) was used in every case. The eye was washed daily with boric acid solution and atropin was instilled. In some cases the bandages were removed in five or six days, and in others not until the fourteenth or fifteenth day. No case was confined to bed more than seven days, four days being about the average.

I am indebted to my assistant, Dr. Martin, and also to the resident physicians of St. Mary's Hospital for the very thorough manner in which they carried out antiseptic detail, as in none of the cases was there the slightest evidence of suppuration.

GLAUCOMA.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY DUDLEY S. REYNOLDS, A.M., M.D.

Professor of Ophthalmology, Otology and Medical Jurisprudence, in the Hospital College of Medicine, Medical Department of the Central University of Kentucky; Surgeon to the Eye and Ear Department of the Louisville City Hospital, and the Gray Street Infirmary, etc.

LOUISVILLE, KY.

The term glaucoma, which formerly meant sea-green pupillary reflex; with more or less complete blindness, described by Walther as a condition in which the patient sees nothing and the surgeon likewise nothing, has come to mean so much that it now really means nothing definite. The nearest approach I could come to a location of the structural lesions which give rise to the symptoms of glaucoma would be the ciliary region of the eye. As a matter of fact, disturbances in the nutrition of the ciliary muscle, with or without corresponding disturbances in the ciliary body, presenting all the varying characteristics from a reflex hyperemia to a fulminating parenchymatous inflammation, give rise to some degree of ocular tension, accompanied by undue fullness of the retinal veins and some degree of depression of the surface of the optic disc. Perimetric registration may be required to complete the diagnosis in some mild cases. In acute inflammatory cases this means of diagnosis, if desired, could not be practiced.

The degree of ache varies from the slightest sense of continued discomfort to a sense of excruciating pain. Clinically considered, the inflammatory attacks of cyclitis which present sharply defined ocular tension, with turbidity of the refracting media, sluggish or entirely absent pupillary movement, with well-defined corneoscleral injection, may safely be accounted manifestations of rheumatism or gout; except-

ing alone those eyes which have been subjected to some recent injury. If iridectomy be done in such cases, it must be supplemented by active antirheumatic medication. I believe it unwise to perform iridectomy during a paroxysm of inflammatory glaucoma. With full dose of Rochelle salts followed, as soon as the bowels have moved, by ten, fifteen or twenty grains of salicylate of sodium in a half pint of water every hour until the pain is subdued; then every four hours alternately with suitable doses of the muriate of pilocarpin in a like quantity of water; accompanying each dose of medicine with four to six ounces of nutrient fluid, such as malted milk, beef tea or other similar fluid, permitting no other nourishment to the patient until all inflammatory symptoms have been subdued (and it may be safely calculated this may be accomplished within two or three days), it will be found that the inflammatory process may be favorably modified, even in the worst cases, within two or three hours from the administration of the aperient. If, when the force of the inflammation has been checked and the humors of the eye cleared up so as to permit satisfactory ophthalmoscopic examination, it then be found that the disc is cupped, the retinal veins enlarged and tortuous, the field of vision characteristically contracted, no matter whether ocular tension is discoverable at this period or not, iridectomy should be done.

In all cases where iridectomy seems to be urgently needed, it must not be forgotten that general anesthesia will be required, and that this nearly always provokes emesis and severe headache; in fact, engorgement of the vessels of the superior extremity of the body, conditions which favor rupture of already turgid vessels. I am convinced many eyes are sacrificed in the hasty performance of iridectomy, before efficient means have been employed to reduce arterial tension. The pain of all inflammatory processes is promptly abated in direct proportion to the reduction of blood pressure. The dangers incident to iridectomy, when blood pressure is high, far outweigh any possible disaster from delay pending the preparatory treatment of the patient. I am persuaded the customary one-fifth, or one-sixth part of the iris is entirely too large a section to remove. I have been frequently amused in reading some of the chimeric explanations of the supposed changes which take place in the eye after iridectomy has been done.

We have all seen in various injuries of the eye, how inflammatory products and traumatic hemorrhages in the anterior chamber likewise disappear. It is no uncommon observation that the glaucomatous eye which has been subjected to iridectomy suffers, with each recurring relapse, more or less hemorrhage into the aqueous chambers. There is every reason to support the theory that drainage through the vessels of the iris into the aqueous chambers constitutes the sole advantage to be derived from iridectomy in the treatment of glaucoma; and there is, to my mind, no tangible basis for the theory that iridectomy is, of itself, a permanent curative agency. I regard it as an absolutely necessary auxiliary measure, in all the varying types of the so-called inflammatory glaucoma. I believe that in the incipient types iridectomy can do no good. I believe it is useless in any case where the iris is not involved. My experience with sclerotomy, both anterior and posterior, has been such as to leave me in doubt as to the value of either form of the operation. I have long regarded Hancock's oper-

ation as an unjustifiable procedure, subjecting the eye, in many cases, to ultimate loss of sight. It is nearly always followed by recurring attacks of cyclitis, which by continuity invade the choroid, eventually extinguishing sight, sometimes requiring enucleation to arrest the frequently recurring reflex disturbances in the fellow eye.

In eyes which have been subjected to extraction of the lens without iridectomy, iritis coming on insidiously, the pupil undergoing contraction and becoming cemented to the posterior capsule of the lens, gradual increase of tension is developed, and even in some rheumatic subjects entire recovery may be secured without iridectomy. In such cases I have occasionally practiced division of the sphincter pupillæ muscle, by passing two needles through opposite sides of the cornea into the minute pupillary area, and by separating the needles, first laterally and then vertically, forcibly tear open the posterior capsule, at the same time divulsing the pupil; following this process by the administration of salicylate of sodium and pilocarpin, in alternate doses, and using locally a drop of homatropin solution every half hour for the first day, always restricting the diet to fluids administered with the medicine, as before suggested, during the period of active inflammatory changes.

An illustrative case may be cited from my practice:

A robust woman 80 years of age, with rheumatic diathesis. I extracted senile cataract from the left eye on April 12, 1897. No incident of importance occurred until May 12, when I received a letter from Dr. N. informing me that Mrs. K. was suffering with neuralgia of the left eye. I wrote to him to use no opiate, but to rely on the salicylate of sodium and the homatropin drops for the relief of the pain. She made but slight improvement and returned to the city on May 21. At that time the ocular conjunctiva was injected so much as to render the sclera invisible. The pupil was about 2 millimeters in diameter, and seemed to be about 5 millimeters posterior to the cornea, giving the iris the appearance of a funnel. Tension +2. On May 22, at the Gray Street Infirmary, I practiced division of the sphincter pupillæ, as above described. The anterior chamber promptly filled with blood and as soon as the operation was completed the patient began with 10 grains of salicylate of sodium in a half pint of water, followed two hours later by one-sixteenth of a grain of muriate of pilocarpin in a like quantity of water; in two hours more, another dose of the salicylate, and so on alternately. At the same time a solution of homatropin, 1 grain to 2 drams of distilled water, was instilled every half hour. On May 23, at 8 A.M., the patient's temperature was 99.3 degrees; at the time of the operation it was 99.8 degrees. The pain, which was considerable at the time of operating, has disappeared entirely, and the patient had a fairly good night's rest, awaking occasionally. At 4 P.M. the temperature was 98.2 degrees, tension of the eye about normal, patient entirely comfortable, in a profuse perspiration; anterior chamber beginning to clear up; iris distinctly visible. May 27, 8 A.M., anterior chamber clear; no tension; pupil distinct and round, 5 millimeters in diameter. Patient had a good night's rest. At 6:30 P.M., temperature was 98.2; aqueous chamber of the eye perfectly clear; vessels of the ocular conjunctiva clearing up, with the sclera distinctly visible on the temporal side of the globe. The lids, which had been slightly swollen since the operation, are now entirely normal in appearance. The patient counts fingers at three feet, and says she wants to go home. May 28, at 4 P.M., the sclera shows distinctly; the eye is perfectly comfortable and the patient is anxious to return home. She has no abnormal temperature and desires a more liberal diet. The pilocarpin is discontinued and the salicylate is to be kept up every four hours. Patient may have a little solid food, the fluid nourishment to be continued with each dose of medicine. The homatropin drops are to be continued every four hours. I regard the patient as safely convalescent and anticipate no further trouble. [August 25, 1897 with +11.00 D.; S. = 6 xii+ Snellen.]

I have had many similar experiences, and submit this as my most recent, as affording, perhaps, the most distinctly typical illustration of my point, that con-

stitutional treatment is vastly more important than either iridectomy, or any possible advantage from local medication.

In an eye from which the lens has not been removed, conditions similar to those described in the case of Mrs. K. could not, in my judgment, be overcome without iridectomy. In an aphakial eye abundant experience shows that iridectomy can accomplish no good purpose and is wholly unnecessary, even in the presence of an acute inflammatory glaucoma.

To briefly sum up the points I desire to make, it will be necessary to keep in mind the clinical features. My conclusions briefly stated are as follows:

1. Incipient glaucoma is frequently relieved by improved nutrition, with correction of any existing errors of refraction. It is sometimes relieved by the iodid of potassium, associated with the local use of eserine drops.

2. Mild and insidious cases of inflammatory glaucoma, between paroxysms, may exhibit but little tension. They require iridectomy for the drainage of the engorged vessels during the paroxysm, and constitutional treatment to aid in the elimination of accumulated debris in the tissues.

3. Inflammatory glaucoma, excluding the traumatic cases, should be accepted as a manifestation of rheumatic diathesis; and, while iridectomy should constitute a necessary part of the treatment, it should not be relied upon to the exclusion of the all-important constitutional measures. I do not think iridectomy should ever be done as a prophylactic measure simply.

4. Since iridectomy can accomplish nothing beyond the establishment of drainage for the vessels of the iris and contiguous structures, into the aqueous chamber, the amount of iris removed should be small. The operation should not be repeated in any case. Supplemental constitutional treatment is imperatively demanded in every case where iridectomy is done.

5. In all cases of increased tension of the eye, with peripheral contraction of the field, engorgement of the retinal veins, with or without visible cupping of the disc, constitutional treatment is necessary; and, above all, strict attention to the state of general nutrition and habits of the patient.

SECONDARY GLAUCOMA.

Presented in the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY S. D. RISLEY, M.D.

Professor of Diseases of the Eye, Philadelphia Polyclinic and College for Graduates in Medicine; Attending Surgeon Wills' Eye Hospital.
PHILADELPHIA, PA.

It is probable that under the title of this paper might be quite correctly classified all classes of inflammatory glaucoma whether acute or chronic. There would then remain a comparatively small, illy defined group of cases of a non-inflammatory type to be designated as simple or primary. Increasing clinical experience has surely taught that the increased tension of the eyeball, the insensitive and steamy cornea, the impairment of peripheral and central vision is a group of symptoms frequently occurring as a resultant of widely diverse pathologic processes. For example, we find this important and interesting symptom-group as a sequel to hemorrhagic retinitis, or to chronic but steadily advancing disease of the uvea in gouty subjects. We meet it again in cases of dislocated lens,

or following large rents in the lens capsule caused either by discission operations or by accidental traumas, which cause a rapid swelling of its substance and speedily loading of the aqueous with the dissolved cortex: It not infrequently presents itself as a part of the closing scene in the destructive processes which characterize plastic iridocyclitis, fiercely attacking, as they do, the anterior segment of the globe, or in uveitis, which involves usually the entire uveal tract. In all of these widely differing conditions the glaucoma group of symptoms occurs as a sequel, probably never as a primary or initial condition.

I do not propose to discuss these suggestions in all their bearings, but simply to give briefly the history of two cases which illustrate widely diverse types of disease, each leading up finally to the symptom-group we call glaucoma.

Case 1.—Plastic iridocyclitis, annular synechia, and occlusion of pupils. Secondary glaucoma, iridectomy; recovery with moderate vision.

W. W., colored man, aged 32 years, came to the Wills' Eye Hospital, June, 1894. He had suffered from an attack of iritis, probably syphilitic, in 1884, since which time he suffered frequent attacks of pain and redness of the eyes, for which he had received no treatment. His vision had gradually failed until he found it difficult to do his work, that of a farmer. During these years he had suffered from frequent attacks of headache, which had lately become constant, and his vision was often so poor that he could with difficulty find his way about in strange places. O. D. V. large letters at 1 m., but was often much worse. O. S. V. q. p. l.

The following conditions were noted: O. D. pupil small; annular synechia; anterior capsule gray; anterior chamber shallow and angle closed by adherent iris. Tension 1. Slight ciliary injection; no study of fundus possible; contracted field of vision. O. S., same general conditions present, but pupil was in addition occluded by a mass of exudate. The iris was pressed forward and was lying apparently in contact with the cornea, the pupil lying in the apex of a funnel-like depression. The ball was soft. He was placed on mercurial inunctions and eserine; potas. iod. in ascending doses internally. This treatment was maintained until the latter part of September. During this time, although his health improved, he suffered severely from headache and had repeated attacks of increased tension in both eyes. His vision grew rapidly worse, so that he was led to the clinic by his wife, and the candle fields were contracted to a few degrees. He was then admitted to the hospital and a broad iridectomy made upward in both eyes. It was impossible to carry the point of the keratome between the cornea and iris. It was therefore entered well back and penetrated the posterior chamber, being brought forward through the iris into the anterior chamber near the pupillary border, care being exercised to avoid the lens. A quantity of viscid yellowish fluid exuded from the wound. The iris forceps were introduced and seizing the iris at the cut portion near the pupil was gently drawn out of the wound in the reverse order from that ordinarily employed. It was found sufficiently tough to bear traction in the right eye, but very friable in the left, so that it was taken away in fragments, but a large coloboma was secured in each, which fortunately remained open. The eyes healed promptly but continued red and irritable for many weeks. The anterior chambers resumed their normal depth and both balls became soft. The headache promptly disappeared and he was soon able to see his way about the ward.

After six weeks he was discharged from the hospital with sufficient vision to be able to go home without a guide, and became an out-patient. Potas. iod. and bichlorid of mercury alternating with iod. of iron were continued with more or less regularity for a year or more, with local washes, atropin and weak solution of eserine. He has never had any recurrence of headache, or pain or redness of his eyes, and the tension of the balls has steadily improved. He attends the clinic without a guide and is able to resume his work about the farm.

Case 2.—Uveitis, secondary glaucoma.

Sept. 9, 1894, R. W. presented himself at the Wills' Eye

Hospital for treatment. He was suffering from dull headache and photophobia. He related that the left eye became red and painful during the summer of 1894, and had been under the care of his physician for a long time before he observed failing vision in the right. He denied syphilitic infection at any time, but was evidently in ill health and of a so-called strumous diathesis.

The pupils were dilated with atropin prescribed by his physician. The following objective conditions were noted: In O. D. there was some ciliary injection, the epithelial surface of the cornea was normal, but the posterior surface was dotted with numerous gray points which were arranged in a more or less triangular form in the lower part of the membrane of Descemet. The anterior chamber had normal depth, but the aqueous humor was slightly turbid. Viewed through this and the deposit on the cornea, the iris seemed to lack luster and its surface presented an apparently smooth uniform surface. The pupil was dilated; large medium and no synechia were present. Only a veiled view of the fundus could be obtained. There were floating vitreous webs, and the nerve borders were lost in the surrounding infiltration of the fundus. T. = n. V. = 6 xii. Field for form normal.

In O. S. there was more pronounced ciliary injection. The cornea was found steamy throughout and at its lower part a large crescentic area extending from the limbus to a point near the horizontal meridian of the cornea, exhibiting deep gray infiltration over which the cornea appeared flattened, but the epithelium was intact.

The anterior chamber had apparently normal depth. The pupil was small, its margins partially adherent to the anterior capsule was gray. V. = 6 xxx, slight minus tension. No satisfactory study of the eye ground could be made.

He received potas. iod. and corros. sub., with tonics, internally and atropia locally. By November 11 the eyes had lost their injection and dread of light and his headache was better, but vision in O. D. had fallen to 6 xv and small slender synechia had formed, and the vitreous degeneration had also advanced. In O. S. V. 6 xlvi; tension and fields were normal in each eye. The atropia was stopped. On November 23 the corneae were steamy and vision had fallen to 6 ix in each, and severe pain in the eyes came on daily, after noon, for which he received eserine locally and antiperiodic doses of quinin. There were transient attacks of increase of tension, but these would disappear after massage and instillation of eserine, even while waiting in the clinic room. The eserine alone however was not well borne, the eye often doing better under atropin, or the two drugs used alternately. He would have intervals often extending over many days of freedom from pain, during which the haze of the cornea would be absent and the vision would improve; then suddenly, and without known provocation, the symptoms would return with marked increase of tension, which could always be speedily relieved by manipulation and eserine. The case progressed until Feb. 11, 1895, when under an unusually severe exacerbation of acute glaucoma, vision fell to the ability to count fingers with difficulty, corneae steamy and insensitive, T. + 1. Severe pain, anterior chambers normal depth.

He was admitted to the Hospital, placed on mercurial inunction, eserine and light massage. Under this treatment, with extra diet and tonics, the glaucoma rapidly disappeared and vision once more came up, but there was marked cut in the lower temporal fields of both eyes.

On March 6 the eyes were nearly white again, and although there were transient attacks of increased tension, the eyes were free from pain. On March 12, 1895, the fields were found as shown in Fig. 2, a and b. O. D. V. = fingers only. O. S. V. = 5 lx. A broad iridectomy was then made in the right eye. The recovery was rapid and without reaction, and in four weeks V. = 4 lx. On April 1 an iridectomy was made on the left eye, which also recovered without reaction, and the man was discharged from the hospital on April 15, 1895, with both eyes white, the fields of vision nearly normal. T. - 1. O. D. V. = 4 lx. O. S. V. = 4 lx. No satisfactory study of fundus possible, cornea clear, except lower quadrant in the left eye. There was no return at any time of increased tension, but there were repeated attacks of bullous keratitis in both eyes, during the following summer and autumn. The eyes, however, finally became quiet. A year later, March, 1896, V. had fallen to 1-60 in O. D. from commencing opacity of the lens. O. S. had risen to 6 xlvi. In April the right ball was soft, lens opaque, q. p. l. shallow anterior chamber. O. S. V. 6 xlvi and white T. - 1. in each eye.

The history of these patients is presented as illustrative of two essentially different groups of patients, both unfortunately very common, but, in the opinion

of the writer, of great interest because they shed much light upon the etiology of increased tension. In both cases was witnessed the steady progress of disease culminating in all the signs of inflammatory glaucoma. Increased tension, steamy and sensitive corneae, and contracted field of vision, all the symptoms being promptly relieved by iridectomy. Nevertheless they present few if any other features in common. In Case 1 was present all the conditions of a plastic iridocyclitis, viz., an acute iritis followed by frequent recurrence of milder or subacute exacerbations, leading to annular synechia, occlusion of the pupils, infiltration of the iris and ciliary body, with the products of inflammation, copious exudate imprisoned behind the iris, which was pressed forward by its accumulation, effectually blocking the spaces of Fontana and thus closing the excretory channels at the angle of the anterior chamber.

In case 2 we have presented a history which differs from case 1 in all essential particulars. The marked tendency to a plastic exudate is absent. Only a thread-like synechia was formed. The onset of the disease was insidious and steadily progressive, attacking first the left eye and after many weeks spreading to the right, where the first manifestation was that of dimness of vision, which proved to be due to an infiltration of the retina and choroid at the posterior pole which blurred the optic nerve margins and veiled the details of the fundus; then degeneration of the vitreous body, shown first by a sand-like deposit and later by webs which as the disease advanced became more dense and floated more and more freely, while the acuity of vision rapidly declined. Then came deposits on the posterior surface of the cornea from the aqueous, which became turbid from the increasing exudate. Not until this stage of the disease was reached was there observed any tendency to increase of tension. At no stage of the affection was the anterior chamber shallow, or the angle closed by the periphery of the iris; at no time was there any arrest of communication between the posterior chamber and the spaces of Fontana. Nevertheless as in case 1, we observed, late in the disease, the increased tension, the steamy and insensitive corneae, the contracted fields of vision, also relieved by iridectomy never to return.

It is obvious that from the start to finish we have two essentially different types of disease portrayed in the history of these two patients, both, nevertheless, culminating in a common group of symptoms depending upon a mechanical condition which required for its relief the same mechanical interference. Many important and interesting inquiries present themselves for discussion, especially in case 2. First, in both interest and importance, is the nature of the disease in the right eye. Was it idiopathic, or was it secondary to that in the left eye which was first involved, and probably due primarily to an abscess in the lower part of the cornea?

In the second eye the disease certainly manifested itself first in and around the papilla and subsequently spread forward gradually manifesting all the conditions ordinarily present in so-called sympathetic ophthalmia of the serous type.

In case 1 the increase of tension was obviously due to the exudates and fluids imprisoned behind the iris and by the closure of the angle of the anterior chamber. In case 2, it is probable that the anterior excretory channels were clogged by the profuse albumin-

ous exudate. This view seems to find corroboration in the relief which was frequently afforded by massage.

DISCUSSION ON PAPERS OF DRS. REYNOLDS AND RISLEY.

Dr. ALLPORT of Chicago—In discussing the paper of my friend, Dr. Reynolds, and while agreeing with him in the general trend of thought contained within its pages, I can not but feel that his loyal, broad and radical nature has been led into certain positive statements that are hardly warranted by the condition of modern ophthalmologic thought. For instance, he utterly surrenders to the rheumatic or gouty theory of glaucoma. I would not be understood as ignoring this important and suspicious etiologic factor, as we are doubtless all firm believers in its potency, but I am not prepared to accept the sweeping assertion that the production of glaucoma is dependent upon two factors, viz., lithemia and traumatism. Time and research may, it is true, verify this bold position, but I am at present unacquainted with scientific data upon which to build such an etiologic structure. The lithemic theory of pathology is now ascendant, not only in ophthalmology, but in other branches of medical science, and like other theories, is in danger of too great popularity; and while not desiring to decry its claims, I would like to be confident that ophthalmology may not be compelled to retrace its steps.

Dr. Reynolds' theory of the cause of benefit derived from iridectomy is, unique. He evidently believes that glaucoma is purely a vascular disease and has nothing to do with abnormal secretion or excretion. He may be correct in his views; it is unbecoming in any one to disregard the opinions of others, but surely this is not the pathology entertained by modern ophthalmologists.

Dr. Reynolds attributes the benefit derived from iridectomy to the mere production of a cut iritic surface which permits of vascular drainage through the iritic blood vessels. If this were true, a simple incised wound of the iris would answer the purpose as well; and how can we account for undoubted (if infrequent) beneficial results following the operation of sclerotomy? I had supposed that the usefulness of a broad iridectomy in these cases resided chiefly in the tearing away of the obstructive, adherent iritic periphery from the posterior corneal circumference, thus re-establishing the lymphatic circulation coming from the ciliary body, zonula, posterior and anterior chambers and going to the canal of Schlemm, spaces of Fontana, and onward. If this is true (and it appears to be the present accepted theory), then Dr. Reynolds' idea of a small iridectomy would be at decided variance with it. We all feel that a large broad iridectomy is the proper operation, as the broader the detached base, the more thoroughly will those obstructions be removed which militate against the maintenance of ocular, excretory equilibrium.

Dr. Reynolds says that iridectomy is of itself never a permanent curative agent. He may be right in this view, but I am sure we can all of us point to cases where a timely iridectomy has proven curative, at least for many years. Such results must surely have occurred, many years ago, before the deadly lithemic diathesis was discovered, or iridectomy would not have become so popular with Graefe and his followers.

Dr. Reynolds certainly holds optimistic views concerning the constitutional treatment of glaucoma, and I must congratulate him on the excellent and exceedingly prompt results obtained in his cases, which I can quite readily comprehend, not only because they are vouched for by my friend Reynolds, but because I have seen similar cases in my own practice. I feel, however, that we should be careful not to pronounce cases of glaucomatous tendencies as true glaucoma, and thereby perhaps establish lines of erroneous therapeutics. Still, I have not the slightest doubt that the sensible treatment advocated by Dr. Reynolds is often of the greatest benefit in *functional* glaucoma, before organic changes have occurred, and I believe that in almost all cases such or similar treatment should be thoroughly tried before subjecting the patient to the knife.

Dr. F. C. HORTZ of Chicago—Dr. Risley's report is an excellent illustration of the futility of the attempts to discover the complex, pathologic symptoms leading up to glaucoma. If we still consider increase of tension as the fundamental symptom, we must necessarily conclude that this may be caused by increased secretion into the eye or diminished excretion from it. We all know that one of the theories is based upon a mechanical obstruction in the iris angle. Among the cases Dr. Risley reported, one illustrates a mechanical impediment interrupting the removal of the fluid from the spaces of Fontana by blocking up the pupil. As to the other theory, which

puts the obstruction in the iris angle, I have never been able to make up my mind to accept it and I think all the observations made and reported of old glaucomatous eyes are very deficient in their conclusive evidence, because in all the eyes examined changes had occurred which had nothing to do with the primary condition leading to the increase of tension, and if we especially consider those cases of so-called secondary glaucoma we are more and more led to look upon the ciliary processes producing the increased secretion as the seat of pathologic change leading to increased tension.

Glaucoma, or increased tension, following needle operations as mentioned by Knapp, and increased tension following traumas in the anterior part of the eye, show more or less symptoms of irritation in the ciliary region and in this connection I consider the researches of Treacher Collins of great importance. He thinks that the ciliary processes are glandular structures and if these observations are confirmed, we have a very important discovery, because these glands might easily answer for the increased secretion of serum into the eyeball as the result of an irritative condition.

Dr. LUCIEN HOWE of Buffalo—I was very much struck by what a gentleman said to me several years ago, that at regular intervals, two or three times a year, he received articles on glaucoma and he usually noticed that the less the author had of experience, the longer the articles were. I do not mean that the papers we have listened to have not given us a flood of light upon some of the points, but we are too apt to be led into this or that theory that has not a sufficient number of facts upon which to stand. I want to mention two things bearing upon these papers. My attention was called some time ago to the extract of the suprarenal capsule for lessening that kind of injection. It is of decided value. The preparation lasts a very short time unless it be made into tablets, which can be easily prepared. Another point I wish to call attention to is the use of eucain as a local anesthetic, especially where atropin causes the iris to almost disappear. It produces anesthesia and does not produce dilation of the pupil.

Dr. C. A. WOOD of Chicago—There is one aspect of secondary glaucoma which it would be well to bear in mind, and that is its tendency to assume forms which it is extremely difficult to differentiate from secondary optic nerve atrophy, associated with physiologic cupping of the papillæ. A unilateral cupping, sufficiently deep and large to hide the papillary portions of the retinal vessels, is practically always significant of glaucoma whether the other signs or symptoms of the disease be present or not, but in the bilateral cases, unless there are unequivocal evidences of glaucoma apart from these ophthalmoscopic appearances (continued increased tension, pulsating arteries, shallow anterior chamber, enlarged anterior perforating view, etc.), it is extremely difficult to make a diagnosis. Schweigger pointed this out many years ago and furnished numerous instances where cases of simple progressive atrophy, accompanied by occasional doubtful increased tension, had been operated upon with disastrous results. I have seen a number of these cases of so-called "simple" glaucoma and have reason to suspect that the lack of faith expressed by many writers in the treatment (eserin, sclerotomy, iridectomy, etc.) of simple chronic glaucoma, arises, in some instances, from the fact that these cases partake much more of the character of simple progressive atrophy associated with congenital cupping of the disks, whatever that may mean, than of the symptom group described by Dr. Risley as glaucoma.

Dr. S. S. SEABETTER of Birmingham—I would like to refer to the statement made a few minutes ago in regard to the frequency of the disease among the colored people, and the attempt to assign a cause for it. I live in a State where two-fifths of the population is colored and I can recall but one or two cases of glaucoma among colored people, while I think of quite a number of cases among the whites, and I hardly think the condition supposed exists.

Dr. C. F. CLARK of Columbus, Ohio—There is only one point I would like to hear more discussion upon and that is the extent of the iridectomy. It is an old question, but not entirely settled. I have seen a number of cases of good results from very small iridectomy.

Dr. LEARTUS CONNOR of Detroit—There are some facts bearing on the points raised by Dr. Reynolds that are worthy of consideration. I think it is proven that the conditions that Dr. Reynolds alluded to do make changes generally in the interstitial tissue and in this way interfere with the spaces between the anterior and posterior chambers, and knowing how this is done the remedy for it is easy. The reason I think that iridectomy may do this is that it opens up these spaces; I do not think it is the taking away of the iris at all, but that by removing it the obstruction in these spaces is removed and the fluid can pass through readily. As Dr. Risley mentioned, mas-

sage has produced these results. I have seen it myself, and some one has said that electric currents will do the same thing. I think it is desirable to try this also. From my own experience I think we have gone somewhat beyond theory and have some pretty positive evidence upon which to base a rational line of treatment, and in a general way Dr. Reynolds has fairly well stated the methods.

Dr. A. B. RANDALL of Philadelphia—A seeming paradox sometimes produces good results. In Risley's case we had a decided amount of reduced tension in the eye operated upon in contrast to the more usual condition between the exacerbations. We should bear in mind the evidence we have to suppose malnutrition to constitute a factor of very great importance, not always secondary, but often provocative. I recall very well a case that in some ways I might call a glaucoma with decreased tension, a case with both eyeballs soft and one absolutely mushy. I made use of iridectomy for the improvement of nutrition and was gratified with a fairly good result which in view of the fact that the other eye went on to a bad result, enables that man to make his living and even to read slightly with an eye that my colleagues strongly urged nothing could be done for it but enucleation. These paradoxes then might properly engage our attention and we may find some underlying interstitial changes that must always be taken into account.

Dr. G. EDGAR DEAN of Scranton, Pa.—I have read the paper that Dr. Connor refers to and since reading it I have made use of electricity in some of the cases in which iridectomy was not called for, and I have positively seen a very decided reduction of tension in the short time of ten minutes after the application of electricity by applying the negative pole to the eye and the positive pole to the head. I would call attention to the fact that the negative pole must be placed to the eye because I have seen cases in which there was increased tension produced by placing the positive pole on the eye; the direction of the current is important. The points which Dr. Reynolds brings out in regard to the internal treatment, such as the use of laxatives, Hunyadi water, etc., is also important, and I believe the use of salicylate of sodium and pilocarpin are very important points and should not be neglected.

Dr. HERMAN KNAPP of New York—In regard to the theory of glaucoma, that the ciliary body is probably at the bottom of it, is shown not only by cases of increased tension, but in sympathetic ophthalmia as well, but the glaucoma after dissection is true experimental glaucoma and the bodies interfered with are the vitreous and ciliary bodies. The lens capsule has nothing to do with it and in those cases the angle is not only left but is increased; the iris is bulging in the center and retracted at the periphery, so there is no blocking of the spaces of Fontana. These two things should be considered.

Dr. D. S. REYNOLDS of Louisville—The point that I endeavored to emphasize was the fact that in the inflammatory forms of glaucoma the disease most likely begins in the ciliary muscle. We all know the predilection of the peculiar complex form of disease we call rheumatism for the connective tissues and the ligaments. Another point I wish to emphasize is that those of non-inflammatory development occurring in neurotic people are due in a large majority of cases to malnutrition. The other causes I could not consider in the short time at my disposal.

Dr. S. D. RISLEY of Philadelphia—There is probably a distinct relation between the deep anterior chamber in glaucoma following dissection operations, as pointed out by Dr. Knapp, and the presence of vitreous which clogs the spaces of Fontana.

ANGIOMA-MYXO-SARCOMA OF THE ORBIT, WITH REPORT OF A CASE.

Presented in the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY S. C. AYRES, M.D.
CINCINNATI, OHIO.

There is no locality of its size in the human body so rich in the various tissues which may serve as the starting point for the development of tumors, both malignant and benign, of the orbit. In it we have bone, periosteum, muscular tissue, fat, fibrous and connective tissue, glands and mucous membrane, and in the capsule of Tenon a serous cavity lined with a serous membrane. There is also the optic nerve and

a liberal supply of blood vessels. Among the malignant tumors we find carcinoma, sarcoma, myo-sarcoma, and from the internal ocular tunics, melano-sarcoma and glioma. Among the benign tumors we find angioma, erectile tumors, fibroma, myxoma, lipoma, hydatids, serous and bloody cysts, dermoids, osteomata, papillomata, cysticerci and occasionally enchondroma. There are also tumors of the lachrymal gland and optic nerve, and aneurysms of the ophthalmic artery, both traumatic and idiopathic. The orbit is occasionally involved by disease of the ethmoid, the frontal sinus and the brain. The cavity is also of special interest to the general surgeon in concussions of the brain, fractures of the bone of the skull including the sphenoid or other bones which form the orbit and in cases where intra-orbital hemorrhages occur. Taken all in all it is a cavity well worth the careful study of the oculist as well as the general surgeon. This is my apology for presenting a rather rare form of orbital tumor.

Mrs. M., aged 64 years, was first examined by me in February, 1896. She stated that the tumor in the right orbit was first noticed eighteen years ago. It began in the upper and outer angle in the region of the lachrymal gland. Its development was very slow and painless and it was several years before vision in the eye began to fail. It has been in its present condition three or four years but is becoming more annoying on account of the enormous proptosis of the globe. The tumor fills the upper and outer portion of the orbit pushing the eye down. The proptosis is very marked, the eye being so far out of the orbit that the posterior portion of the globe is almost on a line with the bridge of the nose. The motility of the ocular muscles is unimpaired except by the great stretching of the muscles. The media are clear with the exception of the lens, in the lower portion of which is a small opacity. The optic nerve is atrophied and there is a large posterior staphyloma. The eye still retains slight perception of light. Under the skin of the outer angle of the upper lid can be felt a movable gland

which is probably the lachrymal gland completely extruded. On forcibly drawing up the upper lid the outline of the tumor can be seen. It is smooth, rounded, not nodulated, is somewhat elastic but without fluctuation. It has a dense whitish appearance and does not resemble a cyst. The outlines of the tumor can be felt around the orbit, above, inward and below. The lower lid is edematous from the mechanical pressure of the tumor and the globe. The tumor has never given her any pain from its incipency to the present time. The exposure of the globe to the air has been at times very annoying and is gradually becoming more so. Her physician, Dr. Heady, to whom I am indebted for the case, says her health is very good. She comes of healthy stock and there is no history of cancer in the family.

The operation was done in the following manner: the outer commissure was first severed and then the adhesions around the tumor separated. The attachment of the growth over to the outer portion of the orbital wall. Its removal was not difficult and was accomplished without sacrificing the globe, but was followed by excessive hemorrhage. I then decided to remove the eye and packed the cavity to control the bleeding. The wound healed kindly and there has been no return since.

The tumor was ovoid in shape and somewhat flattened on its posterior surface. It measured 30 mm. in breadth, 30 mm. in length and 20 mm. in thickness. The entire surface was smooth and shining with the exception of that portion which was attached to the bone.

The specimen was hardened and examined by Prof. S. P. Kramer who wrote me as follows: "The examination of the tumor handed me proves to be an angio-myo-sarcoma. The section shows a large number of dilated blood vessels with thin walls. The remaining tissue is a combination of sarcomatous cells with a considerable admixture of fibrous connective tissue and a hyaline tissue made up of branching cells and a hyaline or mucoid intercellular substance. These tumors have also been called angio-sarcoma-myomatodes, and have been described by Sattler and others as occurring in the tear gland."

NÆVUS OF EYELID, WITH EXTENSIVE SECONDARY CONJUNCTIVAL INVOLVEMENT.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY G. ORAM RING, A.M., M.D.

OPHTHALMIC SURGEON TO THE EPISCOPAL AND SAMARITAN HOSPITALS.
PHILADELPHIA, PA.

I desire to present, somewhat briefly, the history of a case of absorbing interest, which is at present under my professional care, and which by reason of its serious character and great rarity, will form a proper subject for the consideration of the Section.

On Feb. 13, 1897, through the courtesy of my friend, Dr. J. Cardeen Cooper, a female, M. M., aged 18 months, was referred to me for treatment of a nævus of the right upper eyelid. Dr. Cooper has very kindly furnished me with a history of the case, previous to the date of my examination, the child having first come under his observation in June, 1896, five months after birth. At that time there existed on the right upper lid a nævus of the size of a small shin bark, which the mother stated had grown in about two months, as at birth there had existed only a small mark about the size of a pin's head, near the edge of the lid. There was absolutely no conjunctival involvement, nor any apparent evidence of defective vision.

As the nævus continued to grow, it was operated on by one of the general surgeons of our city, by liga-

tion, and at the time of operation was as large as a small English walnut. Five deep sutures were placed at the base of the growth, which then involved the arch of the brow. In one week it sloughed off, leaving a healthy ulcer which healed rapidly without interruption, but with some contractile cicatrization. For three or four weeks the condition remained apparently stationary, then began the protrusion of the mucous membrane, which gradually reached the proportions which existed when I first saw the case, about nine months after the original operation.

On the skin surface of the lid are several purplish red areas of discoloration, with a number of markedly dilated vessels, between and around which the cicatricial area can be distinctly outlined. There is a cicatricial line occupying the outer three-fourths of the brow, a few hairs still remaining at the inner fourth. The lid is showing evidence of cicatricial ectropion. A number of the lashes at the central border have grown upward and external to this area, for about a quarter of an inch, the lashes are wanting. A purplish red mass projects down from the conjunctival surface of the outer three-fourths of the lid, which at its most pendant portion is about 12 millimeters deep. When the lid is everted, the appearance of the inner two-fifths of its conjunctival surface was normal; the external three-fifths somewhat suggesting the appearance of a mass of granulation tissue, which extended well back into, and involved the retrotarsal folds. The line of demarcation between the normal conjunctiva, and the area of secondary nævoid involvement is very sharply outlined. The many dilated vessels were easily recognized, and there was some evidence of extension into the orbital tissue. The accompanying water color sketch, by Miss Margaretta Washington, shows quite accurately the external appearance of the lid, after a slight contraction, the outcome of the operative procedure adopted.

The little patient is an only child. No history of miscarriage is present upon the part of the mother. There seems to be no inherited tendency to syphilis, cancer or tuberculosis, and the child gives evidence of being well nourished. The fundus of the affected eye shows no abnormality, and the condition of the fellow eye is normal. There are no enlarged vessels at any other part of the body, nor any hypertrophy of the pre-auricular or cervical lymphatic glands.

I have operated on the case five times by electrolysis, twice inserting a needle attached to the positive pole, deeply into the growth, and three times with the insertion of needles attached to both poles. There has been some slight contraction, but the result has

not been markedly encouraging. I have realized the possible danger of performing an excision, and have questioned the propriety of attempting so radical a measure, in consideration of the extensive involvement of the conjunctiva. After the removal of the growth, a plastic operation will be required.

Dr. Wm. F. Norris, who kindly saw the case in consultation, suggested the continuation of electrolysis, and advised against extirpation, unless permission were granted to enucleate the eyeball, if found necessary.

As of interest in this connection, I desire to refer to three cases of naevus, reported by Mr. Simeon Snell, in the "Transactions of the Ophthalmological Society of the United Kingdom" (1893).

Case 1.—A girl of 20, subject from birth to a naevus of lip and cheek, developed at 18 years of age, a small purplish-red tumor of the plica semilunaris, after the lip growth had been operated on. The caruncle was not involved further than its surface was traversed by a series of enlarged vessels.

Case 2 was a boy $4\frac{1}{2}$ months, in whom a bluish tinge was seen through the integument in the upper angle of the right orbit. The depression of this angle was by a rounded elevation about the size of a bean. In addition to this, over the inner part of the sclerotic in the conjunctiva, was a band of narrow vessels, several coils running toward the cornea. Beginning near the plica semilunaris, this band ran directly outward toward the cornea, and then skirting this, it reached the middle line above, and passed backward over the globe, and was lost under the eyelid deep in the orbit.

Case 3.—An adult female with an angioma of the left conjunctiva. The eyelids on this side were normal, but a rounded swelling was noticed moving with the motions of the globe under the upper lid. It was about the size of an ordinary blackberry, of a deep livid color and passed underneath the upper lid. The greater part of the tumor was disclosed in raising the lid and occupied the middle third of the exposed surface above the cornea. It had apparently existed since childhood, but was completely dissected out under ether.

In the first and second cases, the treatment consisted of repeated applications of ethylate of sodium, cocaine being first instilled, and the ethylate carefully applied with a brush, care being taken to confine the application strictly to the part desired to be touched.

In the first case five applications, intervals, one week, removed the growth and in the second, four applications caused it to almost disappear.

DISCUSSION ON PAPERS OF DR. AYRES AND DR. RING.

Dr. S. T. RISLEY of Philadelphia—I have seen no counterpart of the very interesting case presented by Dr. Ayres; I have seen one which aside from the operative interference seems to be a counterpart of the one presented by Dr. Ring. While listening to Dr. Ayres' paper I was impressed by the fact that one must be very much in doubt of the character of an orbital growth in the majority of instances. I have seen no angioma of the orbit, but have seen a large number of orbital growths of one kind or another. I only want to urge in view of this uncertainty, conservative treatment in their management. In two cases that I know of where operative procedures were decided upon, and declined, the growth disappeared under the use of iodid of potassium. I feel, therefore, like recommending conservative treatment first.

The case I referred to as resembling Dr. Ring's occurred in a child only a few weeks old when I first saw it. There was at

the upper and outer end of the left eyelid a bluish tumor the size of a split pea, which when the child cried would become still more blue and very much enlarged. It was obviously congenital. When the child was three months old, they had previously declined any operative interference, the growth occupied the outer half of the eyelid and the eyeball was slightly displaced. When the child was lying prone the tumor became very much enlarged, bluish on the surface, and when it cried violently the distension would lead you to pacify it lest it should burst, the tissue seemed so thin. The child died of an intracranial affection and nothing was done to the eye. I think it was congenital and that its origin was in the orbit.

Dr. HERMAN KNAPP of New York—With regard to cavernous tumors in the orbit I have had some little experience. These tumors, I think, should be extirpated. I treated some with electrolysis, but my success was very poor. They can be removed without fear of hemorrhage. If they are in the lid and do not extend very far back into the orbit you can clamp them and have a practically bloodless operation.

There is another group that is more difficult to deal with, but can be dealt with by extirpation; that is, those that are seen in the lid, but extend also deeply in the orbit. They appear usually in the inner canthus and the lid constricts them so that the portion outside, with that inside the orbit, gives them somewhat the resemblance of the old saddle-bags; they are divided into two portions. I remember a case of that kind in a child that came to me twenty-two years ago in New York. I extirpated that tumor by removing only the orbital portion. It was a true cavernous angioma. I introduced the spatula into the orbit, between the eyeball and the tumor and compressed the afferent blood vessels. I had another case of the same kind in Heidelberg and this has always been my course with these tumors, to extirpate that portion that contains the afferent blood vessels and leave the rest to shrink.

Dr. J. E. WEEKS of New York—These tumors have always possessed a great interest for me because of their congenital origin in most every case and because of their tendency to increase rapidly in the young and much more slowly in the old. I have vividly in mind the case of a child that came to me at the age of three months with a small naevus of the left lid and a cavernous development in the deeper structures. The growth was small and I thought to destroy it by electrolysis. This was tried quite thoroughly and some shrinkage took place, but the deeper growth continued to develop and I soon found that method entirely useless. The patient disappeared for a short time and when I saw the case again the eyeball protruded, the cavernous growth extended to the cheek and I asked for a consultation with a general surgeon, who advised that nothing could be done. I have in a number of cases removed them by extirpation and it seems to me that the advice Dr. Knapp gave me when I was with him is good: "Remove those growths as early as possible and remove them thoroughly for they have a sarcomatous nature." If we examine them we find cells in the trabecular spaces that are decidedly sarcomatous. Originating congenitally, the malignancy is extremely slow, but seems to gain as they advance. Nothing should be thought of but their complete removal and if that is done the tendency to return is nil.

Dr. G. E. DE SCHWEINITZ of Philadelphia—I saw the case that Dr. Ring has described some time before he did, probably six months, and am interested in hearing his result. I think if Dr. Knapp had examined the case then he would have said it was not one for the operation of excision. I advised the parents, after consultation, to let the growth alone for the present, but also explained the chances of electrolysis. If extension of the growth should manifest itself, an operation was advised. I have no experience with the ethylate of sodium. Snell has highly recommended it, but it would be well to confirm his results.

Dr. S. C. AYRES of Cincinnati—I have had a case a great deal like Dr. Ring's. It was a baby three months old, one of a pair of twins, and very delicate. The tumor was in the lower, outer portion of the right orbit. When the baby cried it would fill up and look as if the skin would burst. The conjunctival vessels seemed to have at times a pulsating appearance, though I do not think it was aneurysm. I tried electrolysis with very satisfactory results; there was a great deal of shrinking of the tumor. The baby looked as if it would die if it lost an ounce of blood and so was allowed to return home, and when it returned in October the tumor had not grown. I then resorted to the method of extirpation. It was impossible to get a clamp to enclose it, but putting one-half of the Snellen ring clamp over the skin I made an opening through the skin and dissected the whole thing out, uniting the wound in the skin with sutures placed deep. I have a photograph of that child when 7 years old and aside from a little scar the whole disease is obliterated.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

(Continued from p. 34.)

XIX. DISEASES OF THE URINARY AND GENITAL ORGANS
AND OF THE RECTUM.

The *amputation of the penis*, indicated in gangrene and carcinoma, was often performed with success provided that the inguinal glands were not already swollen. The amputation was in most cases made with the ordinary bistoury or a sickle-shaped knife (C. C. von Siebold). If the cancer was limited to the gland, one could cut through the skin and corpora cavernosa with one stroke of the knife; but if it was necessary to amputate close to the symphysis, more of the skin than of the corp. cav. had to be removed, which was greatly preferred (le Dran) because the latter immediately retracted so that the bleeding vessels could not be found. A few first separated the skin with a circular incision, and drew it back, before the corp. cav. were amputated (B. Bell and Warner), which others however considered as unnecessary (Richter). The hemorrhage from the arteries required ligature, since neither styptics nor compression were reliable enough; by the latter method patients were seen to die from loss of blood, two hours after the operation (B. Bell). But the hemorrhage of the fungous corp. cav. could be arrested by moderate pressure, or by sprinkling it with a powder of colophony or gum arabic. In an amputation close to the symphysis the flow of blood was sometimes excessive; in that case the ligature might fail, but compression with agaricus, cold water (Siebold), or the hot iron (Sabatier) accomplished the purpose. In such cases they advised previously inserting a catheter to prevent the contraction of the stump as far as possible, and in order to be able to seize the decussated vessels more readily (Ollenroth). It was also attempted to apply a tourniquet or a small bandage to the penis (C. C. von Siebold). Immediately after the operation, and until the wound was healed, a catheter was introduced, that the urine might not wet the wound, and the orifice of the urethra contract or entirely close. The fear of hemorrhage led Ruysch to the constriction of the penis. He was followed by Bertrandi, Palucci and Heister, who inserted a silver tube into the urethra, and bound a strong packthread around the member. Sabatier sought to perfect this method by first making the incision into the skin and then inserting a cotton cord saturated with nitric acid. The fearful pain must cause every surgeon to shrink from this cruel operation; it was forgotten until von Graefe again returned to it.

On account of the close relation between surgery and obstetrics in the last century, it may be permitted to introduce an operation pertaining to the latter, which made the greatest sensation a hundred years ago. This was *symphyseotomy*. Indeed, Pineau had suggested the operation in the year 1575, and Cl. de la Couruée of Vesaul performed it in 1655 upon a woman who had died in labor; but both were forgotten. Sigault of Paris rediscovered it in 1768 and made the suggestion to the Académie de Chirurgie that instead of the usual deadly Cæsarean operation in case of a small pelvis, the junction of the os pubis, which often yielded in simple births, be separated and

the pelvic cavity thus enlarged. Ruffel, who was appointed as commissioner by the Academy to make a report in the matter, expressed himself as unfavorable to it, in consequence of which that body deferred its judgment. There the matter rested for several years. Sigault would not admit that he was in error, although even the elder Baudelocque distinctly opposed him, and at his doctor's promotion he once more defended the operation (1773). The illustrious Peter Camper came to his assistance. Attracted by the new idea he made successful experiments on swine and observed that the os pubis united again, and he found the operation very easy. When Louis, the secretary of the French academy, asked him for his opinion he expressed himself in a letter to von Gesscher in favor of the separation of the os pubis as opposed to the far more dangerous and not absolutely necessary Cæsarean section (1774). On the first of October, 1777, Sigault for the first time performed a symphyseotomy upon a Madame Souhot, in the presence of his friend Alph. Leroy. She had a narrow pelvis, with a two and a half inch conjugate diameter, and had already had very difficult deliveries four times, always bearing dead children. Physicians and surgeons, among them even Levret, were convinced that the woman could not bear a living child without the help of the Cæsarean section. As her fifth confinement approached, Sigault, who had previously suggested symphyseotomy, but in vain, was called and he performed the operation immediately. He cut through the soft parts from somewhat above the os pubis almost to the labia, inserted his finger along the symphysis and separated the ligament and cartilage. At this moment the two parts of the os pubis separated themselves two and a half inches! He then opened the sac and removed a living child. The entire operation lasted scarcely five minutes. On account of defective light he had inadvertently injured the neck of the bladder. In sixteen days the wound of the symphysis was closed, and in forty-seven days the woman could walk about. Sigault immediately reported the operation to the medical faculty of Paris, to which body the woman was presented in December. The mother and child lived; but the former suffered from a vesicovaginal fistula and prolapsus of the vagina and uterus, and her gait was uncertain and difficult. The operation made a powerful impression. The medical faculty took it up with enthusiasm, had Sigault's treatment published and distributed, had a silver medallion with the date of the operation struck in his honor, and conferred a pension of 360 livres upon Madame Souhot because she had permitted the operation. Even from the pulpit this great benefaction which had fallen to the lot of humanity, was proclaimed. In the following year Sigault performed symphyseotomy four times, three of which were successful, when at the same time four Cæsarean sections in Paris resulted fatally. But soon a few ill consequences of the separation of the os pubis were made known; the women died or were left with wearisome infirmities. The number of its opponents increased and for years they contended with the greatest violence over the operation, which had become the question of the day. In the Hôtel Dieu in Paris, many experiments were made on cadavers, from which it was established that the small pelvic measure was enlarged only slightly, and that in order to facilitate the passage of the head, the parts of the os pubis must be separated to such a degree that the posterior articulation must

necessarily be lacerated. Sigault was charged with performing the operation when there was no need for it, and it was said that the pelvis of Madame Souchot was not so narrow as he had asserted; it was also doubted if, in his operation, the os pubis had of itself yielded two inches. In Germany, C. C. von Siebold first performed the operation (1778); the child was dead. He was obliged to saw through half of the symphysis, which was ossified (for which purpose Aitken devised the chain saw in 1789), and forcibly separate the os pubis. After a few weeks the woman was cured except a small fistula, and a year later was entirely well; the callus between the severed os pubis could be distinctly felt from the vagina. According to Siebold, symphyseotomy promised to be of use only in one case, when the small pelvic measure was not less than three inches and the head lay forward, and was not unusually large. While Loder and Mohrenheim favored the operation but with limited indications, Richter rejected it entirely, because it did not increase the small pelvic measurement, or did so only at the cost of laceration of the posterior articulation, and altogether was not so free from danger as had been supposed, and resulted in many difficulties. W. Hunter, in England, opposed it and admitted only the single very rare indication when, in case of a large pelvic cavity, the head of the child could not descend so low that it could be reached with the instrument. On the contrary, B. Bell expressed himself very favorably toward it and where only little hope was left he preferred the symphyseotomy to the Cæsarean operation or, indeed, to the use of an instrument. In spite of all the pomp with which this operation had been introduced, in spite of all the endorsements on the part of a few clever men, yet in later years it could never obtain acceptance. Still less success had the so-called pubiotomy of Aitken in Edinburgh (1786), which was never put in practice.

In the treatment of *vesicovaginal fistula* surgeons groped in darkness, for they had turned aside from the only path by which progress was to be attained. Already in the year 1663 Roonhuysen of Amsterdam had made the suggestion to trim the edges of the fistula with a knife or scissors through a speculum, and then unite them by a twisted suture. No one remembered Völter, who (1722) first advised a suture after previously trimming the fistula, and remarked: "This operation, to be sure, will appear to some as strange and difficult, as it is in truth delicate and difficult enough. Nevertheless, I have seen it performed once in the case of a gentlewoman, although it did not succeed." In the main the following treatment was made to suffice. In order to prevent the urine from forcing its way through the fistula into the vagina, a curved catheter was introduced and kept in place by an instrument of Desault. This had the form of a truss whose circle surrounded the pelvic region. Opposite the region of the pubis was placed a plate with a silver staff, to which the catheter could be screwed fast and thus held immovable in the bladder. In order to bring the edges of the fistula nearer together a wick of linen or a bunch of lint shaped like a finger of a glove, covered with elastic gum, was inserted in the vagina. In this way the lower edge of the fistula was brought close to the upper, and the round orifice was changed to a narrow fissure. Desault asserted that he had completely cured old and large fistulae in this way, even after six months or a year.

In case of *atresia of the vagina* an early operation

was necessary, for the menstrual blood might, as Richter said, force its way through the lungs and kidneys. If, as in most cases, the vagina was closed by a simple membrane, a longitudinal or crucial incision sufficed, with the insertion of a plug to prevent a fresh obstruction. But the vagina might be grown together, entirely interwoven by abnormal ligaments, or even completely closed. In all operations the procedure depended chiefly on whether the obstructed part was short or long. In the former case the lancet or a two-edged pharyngotome, with a gradual enlargement by means of wax bougies, sufficed; in other cases Richter made the suggestion that as soon as one felt, in the rectum, behind the symphysis, a sac distended by blood that it be lanced with a trocar, through the rectum. If the mouth of the uterus was closed by a membrane it was opened with a curved trocar; in case of a total symphysis a crucial incision was made.

In *hydrops ovarii*, although the patient might live for twenty years, puncture was the only remedy, and it, as a rule, afforded only a temporary relief, since the sac soon filled again. Often the puncture appeared to accelerate the ulceration of the sac and to precipitate death by exhaustion. In case of a small tumor without much pain an operation was rather avoided. W. Hunter in particular advanced this view; he regarded hydrops ovarii as incurable and guaranteed the longest life to those patients who used the fewest remedies. For the rest, the puncture with a thick trocar was regarded as the best method of operation. Since a relapse was not infrequent a radical cure was also brought into question. For that purpose le Dran advised opening the tumor with an incision four inches long, maintaining a free discharge and making injections. Some successful results were obtained by this method, but many objections were urged against it, as for instance the increased supuration, exhaustion, etc. As its unsuccessful result, according to Richter, was occasioned by the admission of air, he proposed to introduce a trocar and then a bent tube, allowing the latter to remain. In this manner Ollenroth saved his patients. When Houstoun (1724) after making an incision had successfully removed a large part of the ovary, the actual extirpation of the ovary was proposed by de la Porte and Morand. W. Hunter was thoroughly opposed to it; Theden, Schmalz and Callisen favored it, and the last named considered extirpation as the only saving remedy, in case of increased swelling, although he doubted whether a woman would consent to it early enough. That the human body could endure the operation was known from history, where it is related that a German sow-gelder "in his wrath, opened the sides of his daughter, all too much in love, and removed both ovaries," whereupon her desire for love ceased. Pott also had successfully extirpated both ovaries which lay in inguinal hernias. This operation was not perfected during the last century; in the year 1809 the first extirpation of an ovarian cyst was performed by the American, Ephraim McDowell of Kentucky.

Among the diseases of the rectum *fistula ani* possessed the greatest interest. The investigation and classification of the fistulae were in the same state as today. A treatment without operation gave promise of success if the fistula was short and broad and the cause easy to remove. In this way J. L. Petit with mercury cured the fistula in syphilis. The operation was counseled against, if the fistula caused no special

pain and did not grow larger and the constitution was not undermined. Richter also said he had observed the development of a black cataract. As consumption might afterward arise (Dumagie) it was always hazardous to operate upon patients with weak lungs. Pott did not agree with the widely promulgated opinion that a healing should not be attempted in case of cachectic people, because the discharge was salutary for the patients; he said if nature had uses for such suppuration the healing or not healing seldom lay within our power. The treatment of rectal fistula had changed to an extraordinary degree. Every age has had its methods; hot irons, corrosives, injection, enlargement and compression successively prevailed. The operation had become so barbarous that the people had a mortal terror of "fistula cutting." This explains also the fear which Louis XIV. had of an operation for his insignificant rectal fistula; he resolved to allow the operation only after many of his subjects had for years remained uncured by various remedies suggested. His body surgeon, Felix, who had invented the royal bistoury for that purpose, operated upon him successfully in 1687. The incision now became the most popular method and all others retired into the background. Sharp supplied special shears for this purpose. A. Monro, Pott, Savigny and many others devised special knives. Most of these were inapplicable and complicated. Pott's bistoury is sufficiently well known; in Savigny's instrument, one of the most convenient, a pointed blade attached to the side of a slightly curved scalpel, can be projected and drawn back. The operation lost its terror when Pott showed that a simple cut which split the fistula throughout its whole length would suffice, and that the callous surrounding did not need to be cut out as J. L. Petit had recommended. If the inner fistular opening lay so high up that it could not be reached with the finger, then a gorget (Runge of Bremen) was introduced into the rectum, the knife being thereupon inserted and following it into the passage (as in the ordinary instruments of today for the operation on vesico-vaginal fistula and on the ear and mouth cavities, at that time the handle of the gorget was fashioned at an angle so that the hand which grasped it lay to one side and did not obstruct the field of operation). Violent hemorrhages were stopped by cold water, the tampon or hot iron. In the after-treatment, in order to avoid a too hasty closing of the cut, a fine compress of lint or a little linen bandage spread with digestive salve was applied; the plugging up of the wound was considered just as reprehensible as to place nothing at all in it (Pouteau). The ligature known by Hippocrates was replaced by the incision, but was snatched from oblivion by Foubert (1757); P. Camper, Desault and Richter extolled it. For this purpose there was used a thread of hemp, silk, horsehair or a wire of lead or gold, or a gut string. As the ligature caused little pain and no hemorrhage the patient remained free from fever and could go about, and therefore many surgeons preferred it to the cut in spite of the fact that the latter led to quicker healing, especially when the fistular opening was deeply located, in case of chronic diarrhea, in feeble and timid persons and in hospitals, where inflammation prevailed. Only in complicated fistulæ with several openings and callosities was the incision unconditionally necessary. If there were no unusual circumstances Desault used the incision and the ligature interchangeably, often for no other reason than

to show his pupils both methods. In 1780 in no Paris hospital were more rectal fistulæ taken for treatment than in the Charité, because there a ligature was used in operating, while in the other hospitals the incision was preferred. Extirpation of the fistula was abandoned.

Hemorrhoids were considered as varicose distensions of the rectal veins, although in most cases an effusion of blood under the inner membrane of the rectum was said to form the sac. They were not operated on unless it was necessary; but the opinion that the discharge was a critical one which removed injurious matter from the body, and that its obstruction was in the highest degree harmful, as Heister believed, was contradicted (B. Bell). In case of violent hemorrhages a silver tube insulated with linen or a piece of gut filled with water was inserted, or a stricture was made whenever possible. If exhaustion from loss of blood followed, an operation was the only trustworthy remedy. There were three methods, incision, splitting and ligature, of which the incision deserved the preference. The empty sac was cut off with shears in such a way that a small part of it remained, which was to cover the wound and further *prima intentio* and the arrest of the hemorrhage. In this way inflammation, contraction of the intestine and hemorrhage were rarely to be feared. If the hemorrhoids were so high above the sphincter that they could not be brought down through the orifice of the anus, then, according to J. L. Petit, an oval lint-tampon with two strong strings was pushed up past the place where the node was situated. In drawing up the strings the tampon was shortened, became thicker and by virtue of that so pressed the rectum that the node protruded from the anus. The splitting of the skin over the varix and subsequent extirpation of the venal node (J. L. Petit) found but few advocates. On the contrary, in case of large nodes, out of fear of hemorrhage, the ligature was much extolled (Heister, Sharp, B. Bell), and was discarded by others on account of the severe pain and inflammation (Richter). Eradication by means of the hot iron, known even in the time of Hippocrates, met serious opposition. If the prolapsed node became squeezed then it was returned to its position as quickly as possible and if necessary for that purpose the sphincter was split or the mouth of the anus extended with the speculum. The severe pain produced by the repletion of blood or inflammation the surgeons sought to allay by strict diet, application of *cremor tartari* and sulphur, leeches, or a puncture with a lancet; B. Bell recommended a salve of nutgalls and, upon Cullen's advice, the internal use of *copaiva*.

The atresia ani exhibited various forms. If, as in most cases, the anus was obstructed by a simple membrane a splitting or a crucial cut and the removal of the flaps sufficed. If, on the contrary, in normal anus, the rectum was obstructed for some little distance by a membrane, a case which was curable only when the place could be reached with the finger, then it was opened only with a pharyngotome. In case of a deformed anus when the rectum ended in a blind sac the operation was so much the more difficult the further back the sac was located from the external membrane, and the result was often fatal. After the insertion of a catheter into the bladder, proceeding carefully, the surgeon sometimes had the good fortune to be able to trace the sac from feeling the fluctuations. If the intestine was lacking there was no other resort than

to supply an artificial anus after the methods of Littre or Callisen.

Desault first taught the proper treatment of *strictures of the rectum*. Up to that time little heed was given it and it was known only in isolated notes, while most practitioners gave their chief attention to constitutional defects and gave less thought to local affections. They gave antisyphilitic remedies, produced artificial sores upon the os sacrum and thigh, and indeed, extirpated the diseased spot. Desault recommended the tent as a principal remedy for the removal of stricture and the dispersion of callosities. He smeared it with cerate, daily introduced a thicker tent, and in this way obtained the most successful results.

(To be continued.)

SOCIETY PROCEEDINGS.

Tri-State Medical Society of Alabama, Georgia and Tennessee.

Proceedings of the Ninth Annual Meeting.

The President, Dr. W. F. WESTMORELAND of Atlanta, called the meeting to order and it was opened with prayer by Rev. J. B. Hawthorne.

Gov. ROBERT L. TAYLOR welcomed the society to Nashville in an earnest and pleasing address. The President responded fittingly on behalf of the society.

The President then delivered his annual address:

CARCINOMA OF THE BREAST,

In which he deplored the fact that cases are referred to the surgeon too late for operation. He called especial attention to the importance of early diagnosis. Every tumor of the breast is suspicious. All writers agree that inflammation of the breast predisposes to cancer. Traumatism plays an important part in causation. In his experience, when there is a bad family history, the tumor will return. He called particular attention to Halsted's operation. The greatest infiltration is in the skin next the subpectoral and axillary glands. Cells may be widely scattered early. Carcinoma extends through the vessels. The pectoralis minor should be left until the pectoralis major is excised. Everything that looks suspicious in the axilla should be removed. Nerves should be cut, especially if connected with infiltrated glands. Operation should be complete, even to excising of axillary veins. In a case where a complete operation did not seem necessary there was a return in four months. If half can be saved it will be as good as can be expected. No living man can lose only 6 per cent. if the three years rule is observed. Figures are fallacious. The large area if left to granulate and cicatrize, predisposes to carcinoma. As a rule, he grafts within a week. All cancer patients have a lack of red blood corpuscles, the hemoglobin reduced to 90 per cent. When the hemoglobin is reduced 15 per cent. the patient will die. This accounts for many lost after operation with no apparent cause.

Dr. J. B. COWAN said that it was not an easy matter to clean out the axilla. He had seen Abbey cover half the bare surface by undermining the surrounding skin and stretching it.

Dr. R. M. CUNNINGHAM said that we did not know what caused cancer. It spreads by lymphatics. It can not be diagnosed in the operable stage. All tumors of the breast are suspicious. If in doubt, operate. If the skin is undermined too far it will slough. Cancer is rare in the male negro. Cancer of the breast is rare in the negro. When tissue is broken down we will get no good from operation.

Dr. B. SHERWOOD DUNN of Paris, France, said that he fully concurred with the position of the essayist that the operator ought to remove not only such tissue as gave rise to suspicion, but to go further and remove tissue which he was satisfied to be healthy, for the reason that the line of demarcation can not be readily defined. He felt that clinical experience did not support the favorable statistics reported by most operators, and that operations for carcinoma rarely resulted in permanent cure.

Dr. PAUL F. EVE said that if all cancer cells were removed there would be no recurrence. He removes tissue which seems normal. Before regional infiltration, cancer can be removed; then there will be no return. We are looking to the

day when the surgeon will recognize all cancer tissue and remove the same.

In closing the discussion, Dr. WESTMORELAND said that Dr. Abbey today would not try to cover a wound by stretching the skin over it. This is bad practice. In the last year he had a large percentage of cases in negroes, so that Dr. Cunningham's idea, which is also in Warren's "Pathology," is not correct. The axilla can not be cleaned out without removing the pectoralis muscle and cutting the veins which come from the axillary plexus. Drawing up the skin will restrict movements of arm.

Dr. J. B. COWAN, Tullahoma, Tenn., discoursed on the subject of

PSYCHOLOGY,

And said that the subject should be differentiated from mental operations. We ought to know something of this science. We all use it consciously or unconsciously. No man who studies psychology can be a skeptic. All the phenomena we see in the external world are but the result of the co-relation of forces acting on matter properly arranged. He differentiated between the material man, the mental man and the psychologic man.

Dr. G. W. DRAKE said that the differentiation made by the author was correct. We study the relations between body, mind and soul by manifestations. Matter returns to the original condition. Mind and soul remain in an unrecognizable condition until the resurrection.

Dr. J. P. STEWART said that mind from a medical standpoint refers to the mind and is manifested by certain idiosyncrasies, notions, whims, fancies, vagaries, and even manias of our patients. We may by our psychologic influence over certain neurotic patients, restore them to health and happiness by suggestion, hypnotism, mesmerism or Svengalism, get control of their minds by the influence of a stronger mind. He hardly thought that we have much to do with the soul, though the idea of soul and its final end may in some degree cause these psychologic manifestations in our hysteric patients.

Dr. W. FRANK GLENN said he never could understand the triune nature of man. He believed that man's spirit was his ego, his immortal part, himself. He believed that he lived in every cell of his body and when death came his spirit simply abandoned the material residence and advanced to higher spheres of existence. He believed there was a spiritual body which was recognized by spirit just as clearly as a physical body was recognized by a material man.

Dr. PAUL F. EVE asked Dr. Glenn, "What is life?"

Dr. GLENN said that he could not define life, but it might be described.

Dr. G. W. DRAKE said life could not be seen, could only be judged by effects. In a paper before the AMERICAN MEDICAL ASSOCIATION he took the ground that the mind does not become insane. The part affected is the brain. So-called mental disorders are not mental but material. The brain is the part which gets out of order. The mind is the power which controls the brain.

Dr. R. M. CUNNINGHAM differed from Dr. Drake that the mind is simply the power that moves the brain. There is as much mystery in cells of liver forming bile, or of the kidney secreting urine, as cells of brain producing phenomena of mind. The power of each is God-given. Mind is a phenomenon of physical action.

Dr. B. SHERWOOD DUNN said that Darwin's theory was built without foundation, as he failed to account for the first cell. The physiologist fails to show what is the incentive that puts in motion the gray matter in the generation of thought.

Dr. COWAN, in closing, said that we have cell activity in vegetable as well as in animal life. We confound mind with soul. The soul uses the mind. Writers make the mistake of not differentiating. Not a triune man, the mind is simply the instrument used by the soul.

Dr. SEALE HARRIS of Union Springs, Ala., read a paper on "The Arrest of Smallpox in the Vesicular Stage," based on the idea that smallpox would stop after the vesicular stage if there was no mixed infection, the idea being to prevent by applying antiseptics to the skin. Quoting from Bryan and Bibb he related cases. In a case seen by the writer the treatment was a success. It prevented pitting, secondary fever, the intolerable itching and fearful stench of the pustular stage.

Dr. R. M. CUNNINGHAM said the pus in smallpox was a secondary infection, but he did not believe the skin could be made antiseptic, though the case reported seemed to show that the treatment had been a success.

Dr. FRANK TRESTER SMITH said that it was not necessary to render the skin aseptic if the number of the germs was reduced sufficiently, their development prevented or retarded.

Dr. J. B. COWAN related a case where a negro with smallpox lay in a brook an hour, with the result that the disease ran a much shorter course than others in the same epidemic.

Dr. SEALE HARRIS, in closing, said that while we might not prevent absolute pus formation, it might be lessened so as to prevent many unpleasant results.

Dr. LLEWELLYN P. BARBOUR of Tullahoma, Tenn., read a paper on "The Pathology and Diagnosis of Early Phthisis," including in this term the stage where there is a breaking down of tissue. In some the diagnosis is easy, in others it can be made only by investigating symptoms that seem unimportant. Skill is required to appreciate physical signs, but the clinical symptoms will often make the diagnosis. When the patient says he does not raise anything you may get a little the first thing in the morning. Bacilli may not be found in an undoubted case. Hemoptysis is almost certainly due to tuberculosis. Pleuritic pains are characteristic of phthisis; may be absent, as may also increase of temperature. Absence of temperature indicates slow advancement or arrest. Take temperature every two hours, ten to twelve days. If increase is two degrees with exercise, it is probably phthisis.

Dr. PAUL PAQUIN said that the basis of tuberculosis was a battle between the tubercle bacilli and the cells in which they are lodged. The disease may exist a long time before the bacilli are expelled, hence the importance of early diagnosis. This is not so difficult. Early clearing of the throat is important. An important factor is serous pneumonia. Temperature is important, rarely above 101 degrees. This comes late when we have a mixed infection. Malaria may coexist. Look for plasmodium.

Dr. R. M. CUNNINGHAM insisted on importance of early diagnosis, which may be made from clinical signs alone. Bacilli may be in sputum of the healthy. The altered ratio between pulse and temperature is important. Pulse is faster than for temperature. Physical signs show lesions which may not be tubercular. There may be a tubercular nidus with no physical signs. The crepitant r le in apex, unilateral, is diagnostic of tuberculosis. Many cases are treated for malaria, dyspepsia, etc. His postmortems showed tubercular matter fenced off with connective tissue capsule.

Dr. B. SHERWOOD DUNN related experiments where matter taken from the postnasal space in 1,400 cases, showed tubercle bacilli in 856. Many carry bacilli which never develop.

Dr. HAZLE PADGETT emphasized the importance of the slight rise of temperature (100.5 or 101) with perhaps no cough; slight anemia. Examine heart, urine and lungs. An early change in the vesicular murmur is important; compare with other side.

Dr. ANDREW BOYD thought that not enough attention was paid to the minute clinical history, that this is lost sight of by going off to the unknown too much. The microscope is the *sine qua non*, but the subjective symptoms come first, hemoptysis, the pulse (out of all proportion to the temperature), the general malaise, dyspnea, loss of appetite, etc. These come first, then the physical signs, crepitant r le in apex, followed by active physical signs. To sum up, he thought the subjective signs were our first guide, then objective; the physical signs and microscope to dispel all doubts.

Dr. W. F. WESTMORELAND did not think tuberculosis always began in the apex, but was there easiest found. Tubercular skin troubles have increased in his clinics in the last few years, perhaps ten times. He disagreed as to the crepitant r le, which is always associated with pleuritis.

Dr. BARBOUR thought the first lesions were at the apex and pleuritic frictions tubercular as a rule. All can not be expert in physical diagnosis, but all can make diagnosis from signs. The majority get well. Bacilli in sputum sometimes precede physical signs. A weak heart may predispose to tuberculosis. Tuberculin may be used by an expert to clear up diagnosis.

Dr. PAUL PAQUIN of St. Louis read a paper on

SEROTHERAPY IN TUBERCULOSIS.

The use of serums, nature's remedies, seems to promise much, as all other remedies have failed. Tuberculosis is generally a mixed infection. With bacilli we find other germs. The nature of the mixed infection should be determined by the microscope. This is as important as the use of the microscope in the early stage. There is no one treatment applicable to all cases. Treatment should be combined. In mixed infection the serum should be prepared to meet the case. Hygienic measures should be employed, climate in certain cases; altitude is not of much importance, the benefit being due to the presence of ozone. Climate is often tried too late or may remain too short a time. Hydrotherapy is often beneficial by stimulating circulation; also massage. In dieting, animal food is best; cream better than cod liver oil; whisky and tobacco contraindicated.

Dr. L. P. BARBOUR said that climate was not a specific, only an assistant. If better in summer send to a warm climate,

otherwise to a cold. Ozone is not a specific. Baker's experiments tend to show that it is harmful. Send to climate least irritating (from dust, etc.). There is no specific. We must not rely on any one thing, but individualize cases.

Dr. R. M. CUNNINGHAM called attention to the difference between tuberculosis and diphtheria. The former tends to get well by cicatrization, by obsolescence, by discharge; not analogous to typhoid or diphtheria, which are self-limited, hence serum treatment is not analogous.

Dr. L. B. GRADY related a case which steadily got worse under Koch's tuberculin when first introduced in Berlin. With climate and other treatment it matters not if a little antitoxin is injected. He does not believe that there ever has been a case of tuberculosis of the lungs cured. In one case diagnosed as consumption the symptoms disappeared after cauterizing the uvula.

Dr. J. A. WITHERSPOON said that this is an infectious disease, but does not have a period of invasion, no incubation; if self-limited the limit is the grave. He believes in serotherapy and would not say that none ever got well, but would say that none got well except by the inherent power of resistance. He has absolutely no confidence in serum treatment of tuberculosis. These gentlemen get good results: 1. From the fact that some of the cases were not tuberculosis. 2. To the hygienic and other measures is due cure. The bacillus may be found without tuberculosis.

Dr. W. F. WESTMORELAND said that the idea that tuberculosis could not be cured should not be allowed to go unchallenged. Wherever the diseased area could be removed the disease could be cured. In view of the statistics there can be no doubt of the good results from these serums. Climate acts by giving rest to the lungs.

Dr. L. P. BARBOUR claimed that good institutional treatment gave about the same results as climate.

Dr. J. A. WITHERSPOON thought it doubtful if because a man got better in an institution and remained in good condition for a long time and finally succumbed to the disease that we should say he was cured and again acquired the disease.

Dr. L. B. GRADY said that he thought that there had never been any cured. He could even say that some had gotten well. Many had improved and might live to old age, but bacilli would still be found in their lungs.

Dr. PAQUIN said that he had been misunderstood. He had not used the word cure. Had reported the cases as he had found them. Tuberculin is not a serum, but the opposite. Tuberculosis and diphtheria are not biologically similar and may require different treatment. His cases were not under favorable surroundings, were not picked. The methods were open, any physician could visit the laboratory.

Dr. HAZLE PADGETT of Columbia, Tenn., read a paper on "The Causes, Diagnosis and Treatment of Valvular Disease." As causes he especially mentioned acute rheumatism, Bright's disease, violent muscular effort. Diagnosis is by timing murmurs, systolic, diastolic and presystolic. Obscure murmurs may be determined in the horizontal position. Important in life insurance. Exercise may bring out murmur, also forced inspiration, then forced expiration, then suspend respiration. The future of the patient should not be darkened by telling him he has heart disease. Tell some one who is interested in the patient. Many will live years. Aortic stenosis is most dangerous, mitral stenosis akin to it.

Dr. R. M. CUNNINGHAM of Birmingham, Ala., read a paper on "The Relation of the Cause to the Immediate and Remote Results and Associated Lesions of Fractures," in which he gave a study of fractures based on mechanical principles showing that bending, compression and torsion are the usual means of fracture, the lesion in bones, in surrounding tissue and in viscera. In indirect violence injury to the soft parts is less than in direct. We are sometimes deceived in the amount of violence and consequent injury, and prognosis should always be guarded.

Dr. GEO. S. BROWN said that the amount of violence is the greatest factor in the prognosis, but when it is less than enough to cause total destruction of the circulation it is only so as the cause of the infection which is itself the most important determining factor. Mr. Lieter, walking his wards with his class twenty years ago, said: "Gentlemen, I have often noticed that bad contusions not complicated by lesions of the skin nearly always do well, those with lesions of the skin have trouble. I am not able to explain this, but the one who does will make his name immortal." He afterward himself explained it and his name is immortal.

Dr. HAZLE PADGETT related a case bearing on some points in the essay. A man was hit on the head with a mail pouch, he became unconscious and died in five hours. Postmortem showed no evidence of external violence, a hematoma of the right tem-

poral region, right temporal and parietal bone fractures; but no depression. The fracture in the temporal opened internally; a ruptured right meningeal clot about three and one-half by two and one-half, by one-half inches: on the opposite side no fracture but a ruptured pial vessel clot, thin, but about two and one-half inches long by one and one-half inches wide. In the cortex of the right posterior cerebral lobe was a small hemorrhage. Here is an illustrative case showing extensive internal injuries without external evidence.

Dr. J. B. MURFREE said: "In the treatment of fractures the cause of the injury is too little considered. This must necessarily play an important part in the treatment. A fracture produced by great external violence must be treated with great care, and be so dressed as to be inspected, while one produced by muscular contraction may be put up in plaster-of-paris and never inspected until the fracture has united. As stated, a simple fracture will do better than a compound one, but in every fracture, whether simple, compound or comminuted, we must duly consider the force that breaks the bone. I remember a case of fracture of the leg produced by external violence that was bandaged and splinted. The limb swelled and the pressure of the bandage being painful the bandage was cut. The leg mortified and had to be amputated and the doctor was sued for malpractice. We must duly consider the damage done to the soft parts as well as to the bone. A case came under my charge where a leg was mashed on the railroad. An eminent surgeon amputated at the knee joint, but when the first dressing was removed the soft tissues were found to be mortified and in time all the flaps sloughed, leaving the condyles of the femur projecting beyond the soft parts, to be covered by granulation after months of suffering. So we must duly consider the injury done the soft parts from the cause producing the fracture. The force that breaks the bone and its mode of application must be considered in the treatment of every fracture."

Dr. J. P. STEWART related the case of a fracture of the leg from the fall of a tent pole. The patient died in ten hours. Postmortem showed rupture of liver and bruising of internal organs. The force should be taken into consideration.

Dr. CUNNINGHAM related a case, in closing, where there was much injury to the leg and he wanted to amputate but the patient refused. He prognosed death, but the patient promptly recovered. The case that inspired the paper was that of a negro with a fracture into the knee joint in which there was a slough and suppuration, although the skin was not broken. The germs must have been forced through the unbroken skin, hence the importance of rendering the surface aseptic before applying splint.

Dr. J. M. MATHEWS of Louisville, Ky., addressed the Society on "Cancer of the Rectum." He said, in part, that while extirpation was the proper treatment still the application was limited. Authors claim that cases live four, five and seven years; he has a case in Louisville with cancer eight years. The rectum is divided into upper, lower and middle: lower, one and one-half inch. This may be removed. In the middle third it will surely return. The upper third involves the sigmoid flexure. This may be cut out and anastomosis made, but why? He would limit operation to the lower one and one-half inches. Pain is not always present. He doubts if operation prolongs life. Cancer patients live five to eight years. There is an allied condition which can be diagnosed only by an expert of years' experience. The only condition in cancer is to let them down easily with opium.

Dr. J. B. COWAN commended the paper for its conservatism. A few years ago every one was for heroic surgery. Now the pendulum is swinging the other way.

Dr. W. E. B. DAVIS endorsed the position taken by Dr. Mathews and thought life might be prolonged if an operation was performed in the early stage. The difficulty was that most cases came to the surgeon too late, just as cases of cancer of the uterus came after the disease has extended beyond the reach of the knife.

Dr. GEORGE S. BROWN thought that it was the exception for surgeons to operate for brilliancy rather than for the good of the patient, and those who did injured themselves.

Dr. GEORGE S. BROWN of Birmingham, Ala., read a paper on "Metatarsalgia or Morton's Painful Toe." This is an affection of the fourth metatarsal phalangeal joint. The pain is sometimes beyond comprehension. Morton suggested excision of the joint. One symptom is necessity of removing the shoe. The ligaments are so stretched as to allow the bone to press against the nerves. He thinks thin-soled shoes may be a factor in causation. Mild cases may be relieved by a stiff sole. In severe cases the joint should be excised.

Dr. J. A. GOGGANS of Alexander City, Ala., made some remarks on

APPENDICITIS.

relating fourteen cases with thirteen recoveries and one death. He thought that we were a long way from knowing the true primary cause of appendicitis; some thought it due to interference with drainage of the tube. This occurred in most cases and accounted for the pain radiating from the solar plexus, but did not account for the appendicular inflammation. Mechanical obstruction could cause pain and fatal perforation, but foreign bodies were rarely found in a diseased appendix. Fitz, in 300 cases, had found concretions in 5 per cent. Dr. Goggans had found no strictly foreign bodies. Even if found it does not show that they caused the inflammation. He thought that there was something still further to be learned about the etiology, that there is a special germ which causes the disease, that the contents of the intestine became concretions and they as well as foreign bodies became lodged in the tube on account of lessened intestinal secretion and contractility of the muscular walls of the intestine and appendix. When the attack was mild (slight rise of pulse, temperature and respiration), he waited for second attack before advising removal of appendix. If at end of two weeks there was tenderness he advised operation. In that class of cases the mortality was not more than 1 per cent. The more severe cases demand immediate operation unless death is already inevitable from sepsis. Some cases might have the operation under local anesthesia more safely.

Dr. M. C. MCGANNON said that many cases had died of appendicitis unrecognized. The mortality in early operation is 1 per cent.; very dangerous in children. Death is the rule in general peritonitis. He does not believe in waiting in the young; may wait in adults. Not necessary to operate in all cases, but it is a surgical case.

Dr. W. D. HAGGARD Jr. gave an abstract of his paper on the "Treatment of the Stump in Appendicitis." He said that in the last six weeks six patients had lost their lives from appendicitis due, he thought, to deferred operation. Operation should be done as soon as diagnosis is made. He related cases. In one with a temperature of 99, pulse 98, he found a perforation. He described the technique of Deaver of Philadelphia, cutting away the mucosa, amputating the appendix and closing with Lembert's suture.

Dr. W. E. B. DAVIS said that mild cases need not be operated on at the first attack, but all should be operated on who have a second attack. In all cases where this is severe the patient should be subjected to operation without delay, for if such cases are not operated on in twenty-four hours a fatal peritonitis may develop. There are many cases which the surgeon will see after the patient has been ill for two or three days in which it is impossible to know whether the case is one of local or general peritonitis.

Dr. H. HORACE GRANT looked upon the discussion as not merely one of methods, but one that involved the security of human life: too important to dispute about contributory details, definite data must be obtained. If ever the electric rays are so perfected as to show the picture of what lies hidden beneath the tissues in cases of inflamed appendix, the question of when to operate will vex us no longer. Until then some common agreement will greatly help. Other things being equal, *i. e.*, a safe place to operate and a competent operator, the mortality will be less if all cases are cut, but these desirable conditions are only occasionally present. He suggested three rules for guidance:

1. In all cases of fulminating appendicitis, difficult to picture but easily recognized, the operation is imperative at the earliest possible moment, before general peritonitis develops.

2. In mild or moderate cases in which operation is declined or hesitated about, or where conveniences for safety are not at hand, we are justified in waiting thirty-six to forty-eight hours to watch the course of the disease. It is to be understood that while such a course is not always safe, even when it appears to be, yet the danger does not justify an imperative demand nor an incompetent operator.

3. In all cases of moderate severity in which distinct, genuine improvement is not manifest after forty-eight hours, the operation should be demanded.

Dr. J. A. WITHERSPOON asked Dr. Grant whether we should use opium and whether we should use a purge?

Dr. Grant replied that the purge was indicated, the opium was not; it would mask the symptoms.

Dr. LOUIS FRANK believes that as soon as the case is diagnosed it becomes surgical and is no longer medical. Some cases should not be operated on. The desperate cases should be avoided, as they bring surgery into disrepute and make others loth to submit to operation. Symptoms may be relieved by salines, but the pathologic cause remains. Mortality would be less if operation was as soon as diagnosed.

Dr. GOGGANS closed the discussion by saying that he would

treat medicinally mild first attacks; if the second, would operate. Purge aids antiphlogistically by unloading veins.

Dr. HAGGARD said that the diagnosis was much easier now than formerly. He would operate first and give salines afterward. Opiates should never be given in early cases. Operations delayed and hopeless cases bring surgery into disrepute.

(To be continued.)

PRACTICAL NOTES.

An Antifat Diet for Pregnant Women with Deformed Pelvis.—Leusser has been reviving Prochownick's suggestions to secure small children by limiting the patient to a nutritious but antifat diet the last two months, and reports in the *Munch. Med. Woch.* (No. 30) his success, especially marked in one case (conj. diag. 10.5), who had borne eight children, weighing on an average 5,500 grams, labor lasting from two to five days. The result was the spontaneous, easy birth of a child weighing 2,900 grams after two hours' labor.—*Wien. klin. Woch.*, November 25.

Treatment of Surgical Tuberculosis with Gum Resin Euphorbium.—Penières reports the successful treatment of tuberculosis of the ganglia of the neck, of the skin, bones and articulations, with subcutaneous injections of euphorbium in glycerinated water in the proportion of 1 to 4,000. The dose of 1 c.c. is well tolerated even by children, and is increased for adults. The slow effect must not be hastened by too frequent injections; one a week or fortnight is enough. The cure is completed without induration of the tissues. Nineteen cases.

An Office Use for Peroxid of Hydrogen.—A good thing for the physician to have constantly on hand in his office is peroxid of hydrogen or hydrozone. Its properties as a powerful antiseptic are well known. A new suggestion as to its use is for the keeping clean and ready of glassware, such as irrigators, test-tubes, measures, etc., while not in use; one part to four or five of clean water is sufficient; some is left in the vessel until the latter is needed, when it is to be shaken, the solution thrown out, the container rinsed with clear water, giving assurance of its thorough cleanliness.—*The Polyclinic*.

The Absorbing Power of the Bladder.—It is announced from Professor v. Merring's clinic that comprehensive experiments with dogs have demonstrated that the rapidity depends upon the concentration to some extent, and that certain substances are much more readily absorbed than others. Seventy per cent. of a 1 per cent. solution of carbolic acid is absorbed in two hours, and the entire amount in fourteen. Almost 40 per cent. of a 1 per cent. solution of cocain is absorbed in three to five hours, showing the necessity of care in the use of these medicaments. Alcohol, boric acid and quinin were also readily absorbed, but morphin scarcely at all.—*Wien. klin. Woch.*, November 25.

Modern Management of Diphtheria and Croup Cases.—This is the title of a comprehensive lecture of Dr. Augustus Caille, professor of Pediatrics at the New York Post-Graduate School of Medicine. In speaking of fever he says, that the high temperature can be reduced by cold and luke warm sponge and tub baths; to give antipyretic drugs regularly every two or three hours is very bad practice, but one or two doses in twenty-four hours, particularly at night, are serviceable. Among the drugs mentioned in this connection is lactophenin, which Dr. Caille recommends in 3 to 10 grain doses with $\frac{1}{2}$ grain caffeine. Quinin, he says, should never be given as an antipyretic in any but malarial disease.—*The Post-Graduate*.

Glandulen Tablets.—An English firm has produced tablets of glandulen, an animal product prepared in tablet form for medicinal use by Dr. Hofmann of Meeraue, Saxony. Glandulen is obtained from the bronchial glands of freshly killed sheep. Having been washed with alcohol, freed from fat, and dried *in vacuo* at a low temperature, the glands are reduced to powder, to which sugar of milk is added in such proportion that

when compressed into tablets weighing 0.25 gram (3.5 grains), each tablet is equivalent to 0.25 gram (3.5 grains) of the fresh glandular substance. One tablet is given three times a day at first, the dose being gradually increased to five tablets three times daily. Glandulen is stated to have been tried in cases of tuberculosis of the lungs.

The Use of Scopolamin Among the Insane.—Dr. S. Tomasini has employed the hydrobromate and sulphate with equal results. They are injected subcutaneously in dose of from one two-hundred and fiftieth to one sixty-fourth of a grain. Sleep was readily induced, especially in women, in from two to three minutes. The injections are not painful, nor do they give rise to local reaction nor to general excitation. The pulse is regular, but more frequent. There is marked dilatation of the pupils. The sleep is quiet, resembling the physiologic. There are no disturbances nor unpleasant symptoms, as nausea. In maniacal cases and periodic insanity it is a remarkable sedative. Habituation is easily obtained and the dose must be rapidly increased.—*Riforma Medica*.

The Alleged Accidental Discovery of the Value of Hydrochloric Acid in Sciatica.—According to an article in the *Semaine Médicale*, a patient discovered for himself a successful treatment for sciatica, a disease from which he had suffered for several years. He had been under treatment in an Algerian hospital by means of hypodermic injections of salt and water, but without much success. After he had left he bethought him that perhaps the salt was not strong enough and that a stronger preparation of salt might be more successful. He therefore procured some "spirit of salt" (hydrochloric acid) and painted it on the skin, getting rid of his long-standing trouble in a few days. Having occasion shortly afterward to attend the hospital for some other affection, he confided in Dr. Bourlier, professor of therapeutics, how he had managed to get rid of his sciatica. This gentleman thought the plan worthy of trial and employed it in several cases with invariable success. He then told his son, Dr. Maurice Bourlier, who was house physician, and he treated a number of cases with great satisfaction to himself and to his patients. A thesis has recently been published on the subject by Dr. C. Gennatas of Montpellier, on the basis of a dozen cases of neuralgia of the sciatic nerve, all of which were completely relieved by this means. The procedure is simple enough. Half an ounce of strong hydrochloric acid is put in a small cup and a brush is dipped in it and applied over the painful part of the nerve, three or four coats being painted on. The limb is then enveloped in a cotton-wool dressing. Of course the application causes a somewhat severe smarting sensation, but this is quite bearable. A few minutes afterward the skin becomes reddened and hot, and sometimes bullæ are formed which fill with fluid. These, even if they occur, disappear in two or three days. Usually the patient feels better even after a single sitting. The application can be repeated in from twenty-four to forty-eight hours, but not again for several days for fear of producing sloughs. Of course, too, where there are bullæ, they must be avoided in subsequent applications. No serious inconvenience is caused by the hydrochloric acid, such as was experienced when a similar procedure was attempted some years ago by Dr. Legroux with strong sulphuric acid, which was found to be liable to cause extensive sloughing of the skin. The twelve patients referred to were all reported as cured in from three to five sittings, extending over from a week to twenty-five days.

NEW INSTRUMENTS.

A NEW OPERATING TABLE.

BY J. F. BALDWIN, M.D., PROFESSOR OF GYNECOLOGY, OHIO MEDICAL UNIVERSITY, ETC.
COLUMBUS, OHIO.

Some years ago, not being satisfied with any of the operating tables in the market, I had one made of my own devising, which has worked so satisfactorily and been so highly spoken of by my gynecologic friends who have seen it in use, that I have concluded to bring it to the attention of the profession.

The ordinary operating table, if arranged to obtain the Trendelenburg position, is usually quite complicated. The more or less complicated machinery necessary to change the position of the patient requires for its manipulation the attention of the operator himself or of an assistant, and not infrequently there is an uncomfortable hitch in its working. A more serious objection, however, is that if the patient is at a comfortable height for the operator when in the horizontal position, the field of operation is carried completely out of reach when the patient is changed to the Trendelenburg; or if the position is comfortable when the patient is elevated, the reverse is the case when she is horizontal. I have been in a number of operating rooms where this difficulty was only overcome by the use of soap boxes for the operator and his assistants to stand upon.

My first table was made in wood. It was used by myself and also my colleagues, Drs. Reed and Means. After a trial of a couple of years, our experience resulted in finding a few points for improvement. Some two years ago, therefore, I had the table reconstructed in iron and glass, with the suggested improvements added. My friends, Drs. R. B. Hall of Cincinnati, and A. F. House of Cleveland, who had seen the table in its original form, at once ordered duplicates in its new form for their own use, and both have repeatedly expressed themselves as highly pleased with it. I soon became dissatisfied with the glass top and replaced it with metal plates. The latter have left nothing more to be desired.

The construction of the table is perfectly simple, as it is entirely without ratchet, cog, pinion, crank, or other complicated mechanism, while securing all the advantages found in the Boldt, Edelohls, Cleveland and similar patterns. The field of operation is at the same level whether the patient is horizontal or in the Trendelenburg position. It consists of a solid wrought iron frame supporting a hinged top, twenty by seventy-two inches, that can be shortened by uncoupling a foot section, reducing the length to fifty-four inches. Its usual

height when level is thirty-six inches, although this can be changed to suit purchasers.

A principal feature of the table is the hinging of the top in such a manner that with a patient in the recumbent position, the whole is so evenly balanced that the anesthetist with a single hand may depress the head and elevate the hips into the Trendelenburg position.

Any degree of obliquity may be maintained by means of two slotted bars through which a screw rod and crank project, with such an adjustment that a slight turn of the latter will lock the table in any desired position. The main portion of the table top drains to the center into the receptacle placed upon a sliding plate resting in the table frame. That portion of the top upon which the head and neck of the patient rest is hinged in such a manner that when the table is depressed, by means of a curved upright this may be elevated so that the head rests in a horizontal plane. The foot piece is arranged with a

series of slots by means of which the lower limbs may be securely fastened during the progress of an operation.

By means of spring bolts and suitable slots, the foot piece may be elevated as shown in the figure, in which position the table is adapted for operations on the head and neck. With this arrangement almost any desired position may now be obtained with this table.

Two crutches are provided and arranged to be attached to either end of the table. By this means what is ordinarily termed the head of the table, may be employed for perineum and similar operations, in which case that end of the table may be slightly depressed, thus securing good drainage. Generally speaking this forms the best end of the table for gynecologic examinations, uterine, rectal and similar operations, because the table top projects beyond the frame, thus allowing more space for the knees of the operator if in a sitting posture. The

table is securely braced, strongly built and mounted on casters with rubber tires. It is finished in white enamel. Being without complicated mechanism there is little to get out of order. As it is simple in construction, it may easily be cleaned. Even the trough and spout are removable. The joints instead of being painted are either plated or bronzed, thus avoiding the danger to an enamel coat that might be caused by the friction in moving. The positions are simple, all being possible without removal of patient from the table.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JANUARY 8, 1898.

THE NEW NAVY IN ITS MEDICAL ASPECT.

The physician who would be considered a well-informed man in his community, can not be indifferent to public affairs, national and international. State and municipal, and a good citizen takes part in discussing the progress of the Nation among other nations. In the absence of war, the several countries of the civilized world are devoting themselves to the preparation for war, and the engrossing topic today, in our own land as in others, is the creation of what is called a new Navy, and naturally the medical aspect of this new establishment is that which particularly engages the medical man. Hence, the report of the Acting Chief of the Bureau of Medicine and Surgery to the Secretary of the Navy will be read by him to whom battle-ships, citadels, redoubts, superstructures, minor turrets and the like are unintelligible terms. It is gratifying to learn that the Naval Hospitals "are now placed on an equal footing with our leading civil establishments in all that pertains to modern medical and surgical requirements and the necessity of making suitable provision for the equipment of a Naval Hospital Corps becomes more urgent." It has long been known to the profession that the naval medical officer has had to labor without adequate support and that the Directors of Naval Hospitals have only been able to keep them in proper sanitary condition and clinical efficiency by retaining convalescents as nurses and attendants, thus vitiating the scientific value of their returns as to duration of illness and treatment; and commanding officers have complained loudly of

this diversion of enlisted sailors and marines from their legitimate duties, yet the medical officer has had no alternative but to use the means at hand, employing the convalescent, in the absence of others, to care for his sick ship-mates, meanwhile clamoring for an independent corps of qualified attendants, similar to that which now forms part of the Army.

Another grievance of the medical officer of the old Navy, which appears to have been perpetuated in the new, was the location of the *sick-bay* or ship's hospital at the extreme forward end of the berth-deck at the water line, where it was exposed to the impact of the sea upon the bow when under way, to the odors of the paint- and oil-rooms opening into it, to the noise of chain-cables and hoisting-engines in port, and to the intrusion of others than the sick and their attendants. In the construction of the new Navy it is incredible that the Chief of the Medical Bureau has had no say as to the location of the hospital, nor has he been consulted as a sanitary expert about the proper air-space of apartments, and their habitableness. Ships have been constructed and their defects first come to his notice through the reports of individual medical officers ordered to them, and these are embraced in his own annual report to the Secretary of the Navy; and as was to be expected from the lack of professional expert advice at the outset, how lamentable has been the failure to provide adequately for the care of the sick and especially of those disabled in action!

Brief extracts from some of these reports from medical officers afloat may be interesting to professional readers:

Surgeon GEORGE P. BRADLEY, senior medical officer on board the first class battle-ship *Indiana*, says:

"The sick-bay is very small for the size of the vessel and number of men—not more than three persons, exclusive of the bay men, can be properly berthed in it. On the whole the facilities for the proper care of the sick or wounded are very inadequate, particularly as regards space, and call for extension in the construction of future ships. The very situation of the sick-bay, immediately abaft the *head* (latrine) is objectionable, depending on perfect tightness of a bulkhead for protection against the gravest dangers. If certain alterations were made, room for the sick-bay might be found on the main-deck within the superstructure. The sick-quarters used in time of peace, as well as the greater part of the crew-spaces, are entirely unavailable [for the care of the wounded in battle], being entirely unprotected by any armor—the only parts below the water are the orlop and platform decks at either end, which might be arranged for the reception and care of the wounded, are entirely cut off from the fighting parts, no communication through the bulkheads existing below. It is difficult to convey the wounded from the comparatively accessible regions, from others it would be practically impossible. In the four minor turrets the only means of egress is the small port in the side, through which the wounded man would have to be passed, as he could not remain inside, without interfering with the service of the guns. Looking at the ship as a whole, it is evident that the prevailing idea in her architecture was that of a fighting machine, where all other requirements were to be sacrificed so far as necessary to the installation of a very heavy battery with its requisite provision of ammunition and appurte-

nances. So far has this idea been carried that the usual living quarters for even the limited number of officers contemplated and actually detailed for her could not be provided without encroaching on space designed for other purposes. The space for ward room lavatory was encroached upon to furnish a room for a warrant officer. This room owing to its enclosed situation and especially to certain hot-water pipes passing into it is quite untenable in hot weather or a hot climate, as was shown during the first part of August when its average temperature was over 100 degrees F., and its occupant was obliged to pass his nights on deck."

Surgeon W. S. DIXON of the first-rate armored cruiser *Brooklyn* says:

"The sick-bay seems to be an unsatisfactory and ill-chosen place for the treatment of the sick. It is situated in the extreme forward portion of the berth deck and divided by an athwartship bulkhead into two parts. The forward section is so encumbered with stanchions (eight in number) for the support of the weights on the deck above that it will be possible to swing only a single cot at sea if the ship should roll very much. There is space for two additional cots but only when the ship is in harbor. The paint room is directly underneath this section, whose pungent disagreeable odors not only destroy largely the utility of the forward sick-bay but a passage-way must be kept for the painter and his assistants in the after sick-bay. It seems strange that in the construction of this great ship so little thought should have been given to the environments of the sick."

Surgeon C. A. SIEGFRIED on board the first-class battle-ship *Massachusetts* says:

"Those wounded in the turrets can not be taken out while in action, excepting possibly those from the base of 13-inch turrets, who can be treated in near-by passages. From the 8 inch turrets it would be very difficult to remove a badly wounded man, as the ports in the rear of the guns and the hatch below are small. No protected space exists below capable of holding more than a very few wounded men, and as the berth deck forward and aft of the casemate offers the only space for this purpose, transport of the wounded and injured to them could not be done until after battle. The importance of improving the medical department of our naval service is more and more apparent in view of the recent advances in the methods and rapidity of killing and wounding—hence it is advisable to institute a properly trained hospital organization."

Surgeon D. N. BERTOLETTE on board the first-rate protected cruiser *Minneapolis* reports:

"The transportation of wounded to the sick-bay is so difficult that in time of battle it would become impracticable. All transportation of the injured has to be left in the hands of persons not belonging to the surgeon's division. There is absolutely no protection for the injured in time of battle; the only protected places in the ship are in the space below the water line under the protective deck, access to which would be impossible with the ship in action, and under such circumstances the only resource will be to gather the wounded in places where they will least incommode the working of the battery and wait until after the action, and then those who are left, if any, may be attended to properly."

Surgeon S. H. DICKSON on board the second class battle-ship *Texas* says:

"It is greatly to be deplored that no change was made in the location of the sick-bay during the reconstruction of the *Texas*. It still occupies the same noisy and contracted space in the bows of the ship, where the pitching motion is most severely felt. It lies between the forward torpedo-tube compartment and the chain locker and serves a better purpose as a passage-way to the former and a store-room for two torpedoes, which

take up one side, than as a hospital for the sick or a consulting room. But one cot can be swung in it with any degree of comfort to a patient and the battle-plates must frequently be shipped in the ports while at sea, thus excluding all natural light. There is hardly enough room in it to perform any surgical operation requiring anesthesia."

Surgeon P. A. LOVERING reports concerning the first-class battle-ship *Oregon*:

"While the sick-bay is not in the extreme bow of the ship, it is so far forward as to possess practically the same discomforts. The motion is great, and when going at full speed or breasting even a moderate head sea many tons of water are dashed upon the deck overhead. It is unfortunate that in our ships the sick-bays are so generally placed in the part of the vessel which is least fitted for that purpose. The sick-bay is situated in one of the most exposed and vulnerable parts of the ship, which forbids its use in time of action and consequently another station has been assigned to the surgeon. The means for conveying the wounded to this temporary hospital are not satisfactory. Even in the quiet of peace, when no confusion prevails, I have found the transportation of the injured to the sick-bay quite difficult, owing to the narrow doors and passages and many shafts which have to be avoided and which necessitate abrupt turns."

Surgeon E. H. GREEN attached to the cruiser *Marblehead* says:

"I would still urge the necessity of a suitable sick-bay. In a ship that is otherwise so comfortable and habitable the lack of a proper sick-bay strikes me as the one great defect."

In agreeable contrast to these reports, Surgeon W. R. DU BOSE reports respecting the double-turret monitor *Terror*, which is, however, properly an heirloom from the old Navy.

"The provision for the care of the sick is admirable. The location in the superstructure is excellent. The surgeon's station in time of action will be in the wardroom, but a careful study of the conditions likely to obtain impresses me with the conviction that the medical officer must needs be here and there to extend professional assistance where needed. The transportation of wounded through narrow inaccessible turret-ports, along narrow-wing passages with sharp angular turns, can only be safely undertaken slowly and gently and not in the hurry and confusion of an engagement."

The concurrent testimony of medical officers, all of them from twenty-two to twenty-seven years in active service, as to the impossibility of transporting men and officers disabled during action to places of safety where they can receive necessary professional attention and the absence of a proper ship's hospital for their subsequent care on board the model man-of-war, whether it be a first or second class battle-ship, armored cruiser, protected cruiser or unprotected cruiser, makes the need apparent for the *ambulance ship*, which the former Chief of the Medical Bureau, Dr. TRYON, has so urgently and repeatedly advocated during his term of office—a vessel which shall be the common hospital for a fleet or squadron, to which all the injured, both victors and vanquished, shall be conveyed immediately upon the cessation of an engagement, if they shall not have already died of their wounds; for casualties in the future on board ships in action may be expected to be very serious and such as to require immediate attention by the medical officers.

Surgeon SIEGFRIED quotes from the account of one present that "the loss on board the Japanese cruiser *Matsushima*, in its late fight, from the explosion of one large shell alone counted up forty-nine wounded and fifty-three killed." But appalling epidemics and resultant monetary losses amounting to millions have not yet convinced our national legislators that it is the part of wisdom to protect the health of the people in the interior as on the sea-board by establishing a National Health Department which the AMERICAN MEDICAL ASSOCIATION, the American Public Health Association and all the State Boards of Health have united in recommending and urging; so, it is hardly probable that heed will be given to the unanimous voices of all the medical officers of the navy, or that the Chief of the Medical Bureau will be consulted as to medical requirements of the department of which he is the nominal head and exponent. Nevertheless, the medical profession at large can not be indifferent either to the establishment of a National Department of Health for the benefit of the whole country, or to the proper medical equipment of the new Navy, on which way depends its success in the event of hostilities.

THE PHYSIOLOGIC PSYCHOLOGY OF SMELLING.

It is a fact of some interest that while the special senses of vision and hearing have furnished some of the most striking acquisitions of modern physiology, the sense of smell has been left comparatively unstudied by investigators. The reason for this is not difficult to surmise; its organ has no mechanical peripheral apparatus that can bring its study into the domain of physics, nor do the variations of olfaction also follow physical laws like those of color or tone. The problems of its study fall therefore more into the domain of pure physiologic psychology, and the practical difficulties have been so great that few have attempted their solution. The close associations of the sense of smell with those of taste and general sensation, its easy sophistication and common, and indeed almost universal, impairment among civilized people, have added to the embarrassment and aided to discourage physiologic experimentation in this direction.

Within a very recent period it has been commonly taught that odors simultaneously sensed did not form a mixed odor, but were appreciated separately and consecutively. The mutual relations of odors and their shadings and graduations into each other have not been adequately marked, and the whole subject has been heretofore in a comparatively inchoate and unstudied condition. The ambitious but not especially scientific attempt of PIESSE to establish a gamut of odors is of course well known, but has not been taken seriously, and as will be seen recent investigation has shown that odor combinations follow more

the laws of color than those of the tone accords. Thus it has been proved that mixtures of certain odors give rise to new and simple odors, though this was not recognized as an universal law. ZWAARDEMAKER in a memoir published within the last three years has attempted to classify odors and has made a series of nine classes, within some one of which he thinks any odor can be included. Combinations of odors he holds can be resolved into the elements belonging to these separate classes; when the sensation is sufficiently fatigued for one of these another is appreciated, and so on. In some cases he holds that odors do not blend but can be sensed at will by the experimenter.

One of the latest and most satisfactory studies of this subject is that of NAGEL, published early last year¹, in which he attempted to test compound odors without unduly bringing in the elements of fatigue to complicate the question. He criticizes the previous works on the subject and discusses at length ZWAARDEMAKER's views, but does not offer any elaborated classification of his own, nor does he appear to have been satisfied himself as to what are the simple elementary odors, a position which, considering the difficulties and the necessarily more or less subjective nature of the study, is judicious rather than otherwise.

The conclusions he does arrive at are that any two odors may combine to form what is, at least for the moment, a new simple odor, the permanency of the latter being dependent on the fatigue of the organ for the components. The new smell is lasting according as this fatigueability for the original elements is equal or nearly so. With more than two components the conditions for permanency are improved. The compound odor has a resemblance, but not an identity with its components. A mixture thus made, though previously unknown to the observer, can be readily recognized as such when at least one of its component elements is previously known, and the more readily when the olfactory organ becomes fatigued so as to render any one of them more prominent than the others. Continued observation will therefore detect the odor as a mixture, if this was not possible at the first. If this is still difficult, if the fatigue for all the elements is still so nearly alike as to keep up the impression of a simple odor, special arrangements may have to be made to detect them, such as prior partial fatigue of the organ or PASSY's method of successive dilutions.

On the whole the analogies of odor combinations are rather with those of colors than with those of sounds, according to NAGEL's observations, which as the latest and apparently the best conceived method of study in this special line, may be taken as giving the latest scientific facts and views upon the subject. He does not, however, find the analogy quite complete in finding complementary odors that absolutely

¹ Zeitschrift für Psychologie und Physiologie der Sinnesorgane.

extinguish each other, though he finds several instances of close approach to this.

The human sense of smell is probably only an imperfect relic of what it once was in the earlier stages of evolution, but it still has its practical value, and whatever aids to complete our understanding of its physiology is a welcome acquisition. At present much is still obscure, and the field is yet an open one for further research.

RARE COMPLICATIONS OF TYPHOID FEVER.

While some medical men during the last few years have been largely interested in studying the value of recently introduced tests for the diagnosis of enteric fever, other clinicians have not been idle in studying this disease with particular reference to both its common and rare complications. More than twenty years ago one of the first and most valuable contributions to this subject was made by W. W. KEEN in his "Toner Lectures upon the Surgical Complications of Typhoid Fever," and the information therein contained, combined with valuable facts derived from more recent statistics, was utilized in the address which this well-known surgeon recently delivered before the Alumni Association of Harvard University. In most instances the surgical complications of typhoid fever have arisen from the infection of bones or glandular structures with the typhoid bacillus and usually with other infecting micro-organisms which have gained access to the body, and lodgement therein, chiefly because of the debilitated condition of the patient's system. Most of these surgical complications occur toward the end of the disease, or during convalescence from it, and naturally rarely require surgical interference until the febrile process has been arrested. There are other complications, however, of a medical character which have not been so carefully and exhaustively studied and these consist not only in grave disorders of the intestinal canal, but also in nervous and lymphatic manifestations, and further than this it is a noteworthy fact that typhoid fever is an infectious disease which in no way protects either during its course or immediately afterward the patient from other infections, so that other eruptive diseases may occur and various infectious processes may begin. An interesting complication of this kind, which seems to occur more frequently during the actual course of the disease than has hitherto been taught, is erysipelas, which, while it also quite frequently occurs during convalescence, seems to occur as a frequent complication during the progress of the disease itself. A number of interesting studies in regard to it have been published during the last few years, of which perhaps the most noteworthy is that of GERENTE, who collected from various sources 3,910 cases of typhoid fever, and among this number found that erysipelas had occurred as a complication

of the acute stage of the disease, or its convalescence, in sixty-four instances, or in other words in the proportion of about one to every sixty-four cases. This observer also noted, in his Paris thesis for 1883-1884, that females are more frequently affected than males, which is a fact worthy of note when it is remembered that males are more exposed and more frequently suffer from typhoid fever. GERENTE also found that erysipelas as a rule made its appearance after the twenty-first day of the development of typhoid fever and it is also a point worthy of recollection that some epidemics of typhoid have seemed peculiarly liable to this complication, probably because the streptococcus of erysipelas was present with unusual virulence or else by reason of the fact that through lack of cleanliness of the mouth and nasal chambers solutions of continuity occurred in the skin and mucous membranes making an opening by which the streptococcus gained admission to the subcutaneous tissues. This is the more likely when it is remembered that a very large proportion of cases of erysipelas complicating typhoid fever are of the facial form. It is also evident from GERENTE's study that erysipelas occurs more frequently in the grave adynamic forms of the disease, or in those in which the patient is exhausted by an unusually prolonged attack. He also believes that erysipelas usually produces a marked amelioration in the typhoid symptoms, provided that the inflammation is not situated about the face; for when facial erysipelas develops the mortality at once becomes very high, there having been sixteen deaths out of thirty-six cases of facial erysipelas which were collected by him. Probably it is only the phlegmonous forms of the disease which gravely imperil the patient's possibilities of convalescence, for in our experience the milder forms have certainly in no way seemed to delay it. Other cases have been reported by ARMIEUX, THIELMANN and BERTHOUD. In ARMIEUX's case a soldier was affected at the end of his second week of typhoid fever by a purulent otorrhea and three weeks later by a facial erysipelas which began in the auditory canal; this was followed in a short time by an osteitis of the humerus and this in turn by death. In THIELMANN's case there seems to be some doubt as to whether the patient was really suffering from typhoid fever, as before admission to the hospital he was unconscious and the greater portion of his face and forehead were covered with erysipelas. Recovery took place very gradually, but there seems to be reasonable doubt whether the case was not typhoid in type rather than due to real typhoid infection. In the instance reported by BERTHOUD there were marked meningeal symptoms during the attack of the typhoid fever which were followed by very tardy convalescence, the patient's general condition being very unsatisfactory. At this time the scrotum and inguinal region became greatly inflamed and erysipelatous, all the lower por-

tion of the abdomen being involved in the inflammation and, finally, a portion of the scrotum became necrotic, death occurring from exhaustion. The autopsy showed that the iliac and renal veins were involved in a suppurative inflammation, secondary to the erysipelas of the skin.

In addition to this case, FREUDENBERGER has recorded a case in which erysipelas appeared suddenly on both ears in the course of typhoid fever, and another instance of complicating facial erysipelas which was easily controlled and from which recovery took place. MARTINEZ has also reported a case of typhoid fever complicated by erysipelas of the foot and leg, but there seems to be grave doubt as to whether this was a true case of typhoid, or, in other words, whether the typhoid symptoms were not due to an erysipelatous infection. Finally, we find three cases reported by HARE and PATEK in which this complication occurred. In the first a well defined erysipelatous inflammation appeared over the left side of the face during convalescence from typhoid and seemed to be undoubtedly due to the fact that there was great soreness of the skin about the lips and buccal mucous membranes and as these became fissured and cracked they permitted infection. In the second case the erysipelas developed during the third week of typhoid about the bridge of the nose and finally extended over the entire face back to the ears and to the hair on the forehead. In the third case the erysipelas began as a complication during the third week of typhoid and was also facial in type. It is interesting to note that all three of these cases occurred in women, thereby supporting the statement of GERENTE, already quoted, that this disease as a complication is more frequent in this sex than in males. It is also an interesting point to note that recovery took place in each instance notwithstanding the fact that the disease was facial in type and that in no instance was the condition of the patient rendered much more grave by the development of the erysipelas. So far as we know there has been no careful study of post-typhoidal insanity since the publication of HUTCHINSON's classic article in PEPPER's "System of Medicine," which was published some thirteen years ago, but we know from HUTCHINSON's paper, and from other contributions to medical literature, that such a sequence to typhoid fever is by no means uncommon. In rare instances, however, insanity or mania has developed early in the disease and not as a post-typhoidal manifestation and, in one case reported by MOTTET, mania developed so early in the attack that the patient was sent to an asylum before the true nature of his disease was discovered, and HENROT and BUCQUOY have seen the disease begin with the delirium of grandeur. Other cases of pretyphoidal mania have also been reported by MURKISON and by DALY. In both of these cases the mania developed as early as the fourth or fifth day of the disease.

HIGHER MEDICAL EDUCATION IN CHICAGO.

A very important move in the interest of higher medical education was accomplished in Chicago this week by the affiliation of Rush Medical College with the University of Chicago, whereby the College becomes one of the institutions connected with this great University's system.

The College took steps last month, under its terms of agreement with Lake Forest University, to sever the connection held with that institution, in order that the new arrangement may be consummated June 1. The members of the active faculty who were trustees have resigned, and their places will be filled by trustees to be selected by the University.

It is understood that after this year higher entrance examinations will be exacted, and additional requirements for the degree in medicine insisted upon. Moreover, it is understood that the entrance examination will be conducted by an examiner from the academic department of the University.

In our judgment no step has been taken by this flourishing College more far-reaching in its character, nor none fraught with greater consequences to the whole medical profession of the Northwest. Naturally, this may not be immediate, but it is nevertheless certain.

President HARPER announced the new affiliation at the last convocation of the faculties of the University. It is understood that this is the preliminary step toward uniting the College to the University as its medical department. This consummation can not be finally effected until the College shall be freed from debt.

President HARPER said :

It will be of interest to the faculties of the university to learn that at its meeting Dec. 29 the university trustees, in response to a petition from the trustees of Rush Medical College, voted to enter into affiliation with that college. The date proposed for the consummation of the relationship is June 1, 1898, but it is specifically stipulated that the affiliation shall be dependent upon three conditions.

The first condition is that the board of trustees of Rush Medical College shall be reorganized. At the present time a great majority of the trustees are physicians, who are at the same time members of the faculty. This is acknowledged to be an unfortunate arrangement. The new trustees will be representative business men of the city of Chicago, who have no pecuniary interest in the income of the college.

The second condition provided that the requirements for admission to the college shall gradually be increased, until in the autumn of 1902, only those who have completed the freshman and sophomore years of regular college work shall be admitted. This proposition, which had already been adopted by the present trustees of Rush Medical College, is a most significant step in the history of medical education.

The third condition relates to the present debt of the college, which amounts to \$71,000. It is provided that affiliation shall not take place until the debt has been paid.

It will be the aim of the new trustees, with such assistance as the university may furnish, to develop the work of the medical college along university lines. In the history of Rush

Medical College it has always been found that with every increased requirement the number of students has increased. It is not expected, therefore, that the number of students will be diminished by the application of the new requirements for admission. It is confidently believed that collegemen from all parts of the country will be glad to enter an institution to which only college men are admitted.

The history of Rush Medical College during fifty years is one of the most interesting and splendid of any that has been enacted in the educational work of the West and Northwest. Its name today in medical circles is held in high honor. The degrees will be those of Rush Medical College, not those of the university.

The proposed affiliation, however, will at present give to the university a general supervision of the educational policy of the institution. The trustees of Rush Medical College will continue to be an entirely separate corporation. The trustees of the University of Chicago can assume no financial responsibility in connection with Rush Medical College.

This affiliation is a part of the general policy of the university in accordance with which already many institutions stand in close relations with the university. Whether Rush Medical College will ever become the medical college of the university time will show.

It is important, however, to note that even with this affiliation of Rush Medical College the university remains without a medical school of its own. The field is therefore open for some friend of humanity to devote one or two millions of dollars for the endowment of a great medical school, the income of which shall be devoted to special research, with which under any circumstances Rush Medical College would work in the closest co-operation. With the moral assistance thus gained the medical college will place itself in a position which, under ordinary circumstances, it could not otherwise have occupied. In thus lending its aid to the medical college the university performs in part the function for which it was established. In entering into this new relationship with a faculty composed of eighty members, the faculties of the university will join heartily in the wish that even more may be accomplished than it expected.

PATRIOTIC PHILADELPHIA.

Philadelphia, which has long held the pennant as the most faithful and loyal friend of the AMERICAN MEDICAL ASSOCIATION (if any superlative may properly be applied to the many faithful and loyal friends of the ASSOCIATION), has given a new proof of her affection and respect, as appears from the following letter from Dr. HOBART A. HARE, lately Chairman of the Committee of Arrangements:

To the Editor:—At the meeting of the Board of Trustees of the ASSOCIATION held on the last day of the Semi-Centennial Meeting at Philadelphia in June, 1897, it was voted at my request, as Chairman of the Committee of Arrangements, that the sum of \$1,000 be appropriated for the purpose of aiding the Committee in meeting its expenses. The Committee has now settled all its accounts and is glad to report that it is able to return to the Treasurer of the ASSOCIATION the amount appropriated. Acting under instruction from it I have this day sent a check for \$1,000 to Dr. H. P. Newman. The meeting was held therefore without cost to the ASSOCIATION.

Yours truly,

H. A. HARE.

CORRESPONDENCE.

Appendicitis.

RICHMOND, IND., Dec. 20, 1897.

To the Editor:—I desire to endorse the subject matter on "Appendicitis" coming from Dr. Sterman of Evansville, Ind., in reference to "alarming mortality" following operative measures for this accident. I call it accident because it is only recently that the furor of operating in this class of cases has culminated. So that operation is advised too often, which produces the alarming mortality to which the Doctor refers. He refers to some cases, and cases of so-called "appendicitis" occur in many localities. In illustration of cases which may or may not be operated on, are those operated on too soon and those too late, with an intermediate class of cases not operated on at all, viz., those which recover; also those which die because operation was postponed till too late.

I visited five cases during the past summer, two for the purpose of operation. The first was dying when I arrived and there was no operation. The duration after a relapse was eleven days. Postmortem was made the day after death and showed a case of appendicitis, perforation of tube, infiltration into peritoneal cavity, general peritonitis, effusion of serum and pus with an effort at organized lymph, and an effort at arrest or cure at that point. Evidences of general peritoneal inflammation and consequent results were present. There was a time, had it been determined, when an operation might have been successful.

Another case was that of a woman 65 years old, and was well marked as to signs, symptoms, etc. McBurney's point was clearly defined but under careful and skilful management by her physician she recovered without operation, which was my advice, as I went with a view to operate.

The third case recovered without operation, under my own management. The symptoms were: Agonizing pain; McBurney's point distinct. Absolute quiet and anodynes arrested the disease in five days.

In another case a physician of this city was called in consultation. The diagnosis was appendicitis. Symptoms: Localized pain; McBurney's point made out; pain and localized soreness; vomiting; bowels obstructed. Under hot fomentations and opiates the patient recovered in a week with no operation.

The fifth case, Mrs. B., was a well marked case. She was a large, fleshy woman, a hearty eater in health with irregular habits of eating. She was attacked with severe pain in the right iliac fossa, low down. McBurney's point of pain and soreness was well marked. Abdominal pain was diffused. Tympanites was marked in general. The limb of the right side was drawn up to relieve the pain and soreness. Under a careful, yet somewhat protracted treatment, with the most absolute quiet, she slowly recovered without operation, and yet in the consultation I had advised an operation the next morning if no improvement occurred. She has had no relapse.

It so happens that I had been making a careful study of cases reported and what authorities have said (I mean operators) for several years back, and I have had occasion to post-mortem such cases as have died and have found "appendicular trouble" which requires a careful diagnosis to distinguish from other troubles which occur in this region of the body. The differential diagnosis must or ought to be "absolute," using the writer's word, before an operation is undertaken, and then, too, at a period when complications are not sufficient to contraindicate it. Hence, I accept the three first conclusions as laid down by the writer, and also agree to the two last propositions, as these cases will in some degree prove, viz.: 1. That too many surgeons (those who are teachers, i. e., surgical operators) operate too much, that is, they popularize an operation,

which oftentimes in my judgment had better not be made, because patients do more or less slowly convalesce, finally recover and remain well after such attacks. 2. I have seen (in now nearly fifty years' practice) many such cases which we would now classify as "appendicitis," recover without an operation.

Finally, many lives have been lost by an operation made when convalescence had been established and any operative procedure was surely contra-indicated.

Thus I am glad to record my experience as sustaining the experience as recorded by the writer referred to and, furthermore, to suggest that the trend of modern surgical opinion will bear criticism and close examination; when, standing in the presence of a human life threatened with death and appealing to the surgeon for aid, the surgeon must be conservative, honest, backed with a comprehensive knowledge of the symptoms and facts and one who will not yield to temptation; hence, judicial in his mental make-up.

There are three more cases which might be added to this list, one recovering and two dying; one refusing operation under consultation and the second being too late for an operation, which was desired; and postmortem revealed in both appendicitis with peritoneal complications.

Summary.—Eight cases, five recovering and three dying from complications rendering it useless to operate; postmortem in three cases to verify diagnosis. In these cases the percentage of mortality is 37.5; the percentage of recovery 62.5, without operation. "Talamon (Fr.) admits that 90 per cent. recover without operation, taking all forms of the disease." Then why such urgency to operate?

R. E. HAUGHTON, M.D.

Diabetes Mellitus.

MILTON, DEL., Dec. 28, 1897.

To the Editor:—In the JOURNAL of Dec. 18, 1897, you gave us quite an elaborate article on "Diabetes Mellitus," for which the profession owes you many thanks. I have often thought while the scientists were almost turning the world over to unearth a remedy for the cure of consumption, diphtheria, etc., how little has been done about this dread disease. There are reasons for it, and one is they have never satisfactorily solved the why and wherefore, the primary cause; but why has there not been more investigation? For, if there is one disease more loathsome than another it must be diabetes. It deserves our most thoughtful and serious consideration. The authors give us but a faint idea of the disease or how or whence it comes. They speak of sugar appearing in the urine after eating certain kinds of food, or it may appear during many diseases. This we all know and it occurs in every physician's practice; but the primary cause and to get down to the bottom rock, the starting place, there has been but little light thrown upon this great question. Theory amounts to but little when you have to face that dread disease; we get lots of that out of the lectures of professors in our colleges and their writings, but when reduced to practice are of but little worth; but the cause of this trouble is what we are after and how to remedy it. Speculation won't do; no one can treat disease successfully without knowing something of the cause and how to remove it. As matters stand, we are like a blind man groping his way in a strange room where nothing is sure to him. Such, I fear, is the case with many of us, we are too prone to guess at what we don't very well understand and leave the result of our mistakes many times to what is called providential visitations. While it has been considered that the amylaceous and starchy foods had much to do with the diabetic condition, yet we have never known a demonstration of the fact, as we have said before. We often see sugar in the urine after eating certain kinds of food, but that does not go to say that such is the primary

cause. And in our treatment we have always taken the reverse and administered acid and alkalies as an offset, making an attempt to neutralize the sugar: but always making a miserable failure.

Let us hear from you again.

JAMES A. HOPKINS, M.D.

Railroad Rates and the Denver Meeting.

TECUMSEH, MICH., Dec. 28, 1897.

To the Editor: Permit me to correct some of the erroneous impressions which my article of December 11 appears to have made upon the mind of your correspondent of Sioux Falls, S. D., and which find their way into the JOURNAL of Dec. 25, 1897.

In the first place the members of the AMERICAN MEDICAL ASSOCIATION are not mendicants, and therefore do not solicit free passes to the Denver meeting, nor to any other meeting; neither can the writer ascertain that the members of this ASSOCIATION ever had free passes to any of their meetings, at least within the last quarter of a century. Secondly, the members of the ASSOCIATION simply require of the railroads that they give the members a similar rebate which the roads have already conferred upon members of conventions previously mentioned by the writer, and nothing more. This plan, if adopted by the railroads, would meet the approbation of "the average country doctor," as well as the average city doctor, who as a rule has neither money nor time to throw away for the benefit of the public, although he frequently does it, even for the benefit of opulent corporations.

The following paragraph from your correspondent mentioned above is merely quoted in order to show its absurdity: "The railroad company finally kept tab and discovered that in one year free transportation to the amount of about \$60,000 had been called for and used to go to other places than the ASSOCIATION, over and above that actually used in good faith." This statement when applied to the members of the AMERICAN MEDICAL ASSOCIATION is all hocus pocus, without the slightest foundation of facts.

In conclusion, allow me to suggest that hereafter, the Committee on Transportation fix the place of meeting of the ASSOCIATION after they have succeeded in obtaining fair railroad rates to and from that point. Respectfully yours,

J. F. JENKINS, M.D.

License in Germany.

TOLEDO, OHIO, Jan. 3, 1898.

To the Editor:—In Dr. Blech's reply in the last issue of the JOURNAL, he says: An American graduate can matriculate at a German university. That has not been denied, but he is not admitted to the State examination unless fulfilling the requirements as stated in my explanation. He says: The gymnasium embraces a curriculum of seven years only.

The classes are *Sexta*, *Quinta*, *Quarta*, *Tertia B*, *Tertia A*, *Secunda B*, *Secunda A*, *Prima B*, *Prima A*, with one year's course in each equals nine years if one is passed every year, which is not always the case. Age for admission to *Sexta* is 10 years.

As to *Gewerbefreiheit*, those are the quacks, and have no sheepskin of any kind, while the question under consideration is the full fledged license to practice.

These few remarks to show that Dr. Blech's corrections are incorrect, and that there is nothing to change in my primary statements. But now I can not help but pick up one expression found in Dr. Blech's last print, which I hope slipped under his pen without giving it the necessary premeditation. He says, and claims to quote me in doing so, that Johns Hopkins, Harvard, etc., are not considered equivalent to a German University. I most positively must take exception to this

statement, and this with some self-satisfaction to me as a foreign graduate in opposition to a graduate from Barnes Medical College at St. Louis ("Polk's Directory"). Every learned European and German, not even necessarily a physician, knows and admits that *some* of the American schools are fully equal to the European standard, that a large number of American physicians, living and dead, are found among the leaders in the profession, and full credit is given to what Americans have done for the advancement of science. The question of equivalence, however, does not come up at all in legislating for the regulation of licensed practice of medicine; compare the State of New York, etc. B. BECKER, M.D.

An Interesting Case.

SIoux FALLS, S. DAK., Dec. 27, 1897.

To the Editor:—Christmas eve two men engaged in a quarrel in a saloon in this city over a bill. They went out into the street to continue the quarrel. After some words, the larger of the two, who was a large powerful man, struck the other a severe blow in the mouth. Instead of falling backward as would have been expected, the man hit fell forward and his enemy struck him another blow as he went down. He immediately became unconscious, and though his heart was beating when medical aid reached him, respiration had ceased and he was shortly pronounced dead.

All sorts of conjectures were indulged in as to the probable cause of death, it not being thought probable that two such blows as were given could kill a man. Some attributed it to heart disease, others thought his neck must have been broken. The autopsy disclosed the fact that the man when struck had a large quid of tobacco in his mouth and had probably at the instant of receiving the blow taken a sudden and deep inspiration, drawing the tobacco down deep into the larger bronchi, completely occluding them, causing his almost instant death.

The coroner's jury found the man who struck the blows guilty of manslaughter in the second degree. We have heard of tobacco causing death, but never before in just this way.

A. H. TUFTS, M.D.

Medical Courtesy.

CLARKSBURG, W. VA., Dec. 21, 1897.

To the Editor:—In case a physician who is in good standing in his State medical society moves his location to a town in a neighboring county of the same State, in accordance with social or professional ethics, who is expected to first extend courtesies in the way of friendly calls, the new-comer or his older established professional brethren?

Very respectfully, R. A. H., M.D.

ANSWER: Where a physician moves into a neighborhood, courtesy demands that his brother practitioners should call on him within a reasonable time and give him the right hand of fellowship.

Texas Medical Practice Laws.

CHICAGO, Dec. 28, 1897.

To the Editor: Kindly advise me in our JOURNAL as to laws and regulations of practicing medicine in the State of Texas.

"DOCTOR."

ANSWER: A license is issued after examination by a District Board of Medical Examiners. Diplomas confer no right to practice. *See* the JOURNAL, Vol. 22, p. 355.

SOCIETY NEWS.

Therapeutic Society.—At a meeting held at the National Medical College, July 29, 1897, to organize "The Therapeutic Society of the District of Columbia," there were present, Drs. H. H. Barker, G. R. L. Cole, C. T. Caldwell, J. T. Kelley, Jr., L. Kolopinski, D. O. Leech, J. S. McLain, G. C. Ober, W. M.

Sprigg, M. F. Thompson, J. T. Wintern. The following officers were elected: L. Kolopinski, president; J. T. Winter, first vice-president; W. M. Sprigg, second vice-president; J. T. Kelley, recording secretary; G. C. Ober, corresponding secretary; J. S. McLain, treasurer. Article 11 of the constitution says, "The object of the Society shall be the study and advancement of medical and surgical therapeutics in all of the special branches of practical medicine. The Society meets in one of the rooms of the National Medical College, on the second Saturday of each month. The active membership is limited to fifty, and any member of the Medical Association of the District of Columbia is eligible."

J. THOMAS KELLEY, Recording Secretary.

St. Louis Laryngological and Otological Society.—On December 27 the St. Louis Laryngological and Otological Society was formed, composed of those physicians of St. Louis who limit their practice to the treatment of diseases of the nose, throat and ear. Dr. J. C. Mulhall was elected president; Dr. J. B. Shapleigh, vice-president; Dr. F. M. Rumbold, secretary, and Dr. A. S. Barnes, Jr., treasurer; for the year 1898. Meetings will be held monthly, and it is expected that the scientific programs furnished will be highly interesting and instructive. While the membership is limited, the privilege of inviting professional friends is reserved to each member.

BOOK NOTICES.

Transactions of the Medical Society of New Jersey. Cloth. Pages 347. 1897.

This volume covers the one hundred and thirty-first annual meeting held at Atlantic City, N. J., June 22 and 23, 1897. Besides society data it contains the following papers: "The Value of Antitoxin as a Remedial Agent . . . Against Diphtheria;" "Present Status of the Serum Treatment of Diphtheria;" "Headaches; Auto intoxication a Factor;" "A Criticism of Modified Milk and of Modern Dairy Methods;" "Some Important Points in . . . Acute Lobar Pneumonia;" "Scarlet Fever Reproduced by Inoculation . . .;" "Progress in State Medicine and Hygiene;" "Aphorisms on Medico-Legal Testimony;" "Progress in Bacteriology During the Past Year;" "Progress of Ophthalmology and Otology;" "Account of a Patient . . . Who Swallowed Numerous Indigestible Articles with Suicidal Intent."

Transactions of the Medical Society of New Jersey. Cloth. Pages 453. 1896.

This volume contains full proceedings of the one hundred and thirtieth annual meeting held at Asbury Park, N. J., June 23 and 24, 1896. The paper and press work of the volume are a credit to the society, the volume being a companion volume to that for 1897. The contents comprises reports, minutes, etc., and a number of valuable papers.

The Action of the Health Department in Relation to Pulmonary Tuberculosis and the Scope and Purpose of the Measures Recently Adopted for its Prevention. Paper. Pages 70. 1897.

This is a report of the Board of Health of New York City, made to Mayor Strong, and contains much valuable data concerning pulmonary tuberculosis. Several maps of New York wards add to its value.

Proceedings of the Ninth Annual Session of the Association of American Anatomists. Paper. Illustrated. Pages, 65. Washington, 1897.

The volume contains the proceedings of the annual meeting held in Washington, D. C., May 4-6, 1897, including papers presented at the meeting and a number of full page half-tones illustrating the papers.

Biennial Report of the Department of Health of the City of Chicago being for the years 1895 and 1896. Chicago. 1897.

This report is one of the most valuable ever published by the Health Department. Dr. Reynolds in his letter of trans-

mittal says, "The general excellence of the work of the department is due in a large measure to Dr. F. W. Reilly, who was appointed assistant Commissioner of Health by the undersigned in January 1895, and most wisely retained during the last administration and reappointed by the present."

The contents of the volume includes the Reports of the Divisions and Bureaus of the Department, contagious diseases, diphtheria, the anginas of 1896, diagnosis of diphtheria, special medical sanitary inspection, inspection of public schools, work of the disinfecting corps, statistics, tables, circulars, etc., of the contagious disease division, circulars of the department, hospital and ambulance system of Chicago, auxiliary medical corps, report of the municipal laboratory, relation of the medical profession to the water supply, regulation in the practice of midwifery, report of smoke division, report of the City Statistician, report of the attorney for department of health, financial statement by the secretary, roster of the department, vital statistics, mortality statistics.

There is an excellent statement of the new isolation hospital and the ambulance service. Taking it all together the report covers one of the most interesting periods in the history of the department, and may well be studied by the progressive sanitarian.

The Care and Feeding of Children. A catechism for the use of mothers and children's nurses, by L. EMMETT HOLT, M.D. Second edition. D. Appleton & Co., 1897. New York.

This catechism is one of the most valuable of its kind and if placed in the hands of every person that has the care of young children it would be an immense benefit to a great many of the coming generation.

Manual of Pathology Including Bacteriology, the Technique of Post-mortems and Method of Pathologic Researches, by W. M. LATE COPLIN, M.D., being the second edition of the author's lectures on pathology re-written and enlarged. 268 illustrations, many of which are original. Philadelphia: P. Blakiston, Son & Co. 1897. Pages 638; price \$3.00.

The work is divided into three parts, the first part is devoted entirely to the technique of laboratory examinations; part two, general pathology including bacteriology; third part, special pathology.

It is an admirable condensation of the vast subject, which, in view of the several special works devoted to each section, is extremely hard to compress in one volume.

A work of this kind must necessarily be largely compilation, and yet due credit should be given where the language of another author is used; especially is it desirable in the matter of statistical and comparative tables.

We notice for instance on page 211 of this book a table which is headed "diagnostic features of sarcoma and carcinoma," the first half of which is taken bodily from Woodhead's Third Edition, page 607.

Questions are appended to each of the chapters to aid the instructor in class recitations.

Syllabus of Laboratory Work in Materia Medica and Therapeutics in Use at Rush Medical College. By DANIEL R. BROWER, A.M., M.D., Professor Mental Diseases, Materia Medica and Therapeutics; J. A. PATTON, B.S., M.D.; JAMES C. GILL, M.D.; GEORGE W. HALL, A.M., M.D.; C. A. WADE. Pages 286. Chicago: The W. T. Keener Company, 1897.

This syllabus fairly illustrates the change that has taken place in the teaching of materia medica and therapeutics. In the old days, not more than a quarter of a century ago, the professor stood before his class for an hour and gave an address more or less profound, more or less eloquent, according to the abilities and mood of the lecturer. He held up a bottle containing a specimen of the drug or preparation, and as a special favor occasionally passed it around for inspection with the bottle tightly corked and the label duly numbered and recorded. This cursory inspection was supposed to be sufficient to inform the student fully of all that was necessary for

him to know. Now it is different; the student must handle the drugs: must be able to test the qualities from a chemist and as well from a pharmaceutical standpoint. Not only that but he must record his results. For this purpose each student is separately provided with the necessary chemicals and apparatus according to the list duly set forth in the syllabus: the chapters to which are as follows: 1. Desk invoice. 2. General laboratory rules. 3. General instructions for tests. 4. Weights and measures. 5. Prescriptions. 6. Materia exercises on the various official drugs and preparations (190 pages of these exercises). 7. Therapeutics, exercises on electricity, massage, enemata, lavage, hydrotherapy, counter irritation, pneumotherapy, dietaries. Truly, the medical graduate of today has no holiday task to earn his medical degree.

The Psychical Correlation of Religious Emotion and Sexual Desire. By JAMES WEIR, JR., M.D. Second edition, pp. 338. Louisville: Courier-Journal Job Printing Company, 1897.

This book contains separate chapters on: 1. The origin of religious feelings. 2. Phallic worship. 3. Psychical correlation of religious emotion and sexual desire. 4. Psychical problems, viz.: "Psychology of hypnotism, virginity and effemination, borderland and crankdom, the methods of the rioting striker, an evidence of degeneration, genius and degeneration, prophecy and insanity, occultism, etc., effect of female suffrage on posterity, animism and the resurrection, suicide in the United States. Is it the beginning of the end?"

Masters of Medicine. A Series of Monographs, edited by ERNEST HART, D.C.L., Editor of the *British Medical Journal*. Each volume with photographic frontispiece. Large crown octavo, cloth. 1. John Hunter; Man of Science and Surgeon (1728-1793). By Stephen Paget, with introduction by Sir James Paget. Pp. 273, \$1.25. 2. William Harvey. By D'Arcy Power, F.S.A., F.R.C.S. Eng., Surgeon to the Victoria Hospital for Children, Chelsea. Pp. xii-283, \$1.25. New York: Longmans, Green & Co., publishers, 91 and 95 Fifth Avenue.

In the long fight against disease, especially its causes and for prevention, which has so far resulted in increasing the average length of human life to a considerable degree, the lives of those masters who have led in this warfare can not fail to be of great interest.

The names selected by the distinguished editor, Ernest Hart, are John Hunter, William Harvey, Edward Jenner, Sir James Simpson, Hermann von Helmholtz, William Stokes, Claude Bernard, Sir Benjamin Brodie, Thomas Sydenham, Vesalius.

The first two of these volumes are before us, and although much has been written of John Hunter and William Harvey, yet we must say that these volumes add very much to the general stock of knowledge concerning them, and to general literature has added a couple of biographies as entertaining as they are generally useful.

These lives are destined to become English classics and as such read by every physician who desires to be familiar with the progress of medicine and surgery among the English speaking race.

Transactions of the American Orthopedic Association, Eleventh Meeting, held at Washington, D. C., May 4, 5 and 6, 1897. Pp. 296.

This report is ably edited and contains the proceedings of the last annual meeting and the papers read at the meeting by the members of this society.

The work is well illustrated and handsomely printed. The historic address of the president, Dr. Samuel Ketch of New York, is one of the features in the volume of interest to the general profession. The book compares very favorably with its predecessors and is very creditable to the Association.

What a Young Man Ought to Know. By SYLVANUS STALL, D.D. Philadelphia: Vir Publishing Co. 1897. Price \$1.

This book is to be commended from a moral and from a sanitary standpoint. One is apt to be prejudiced without reason

against books of this class and we confess a weakness of that sort, but on perusal we not only find nothing from which to dissent, but very much to commend. The chapters on marriage are specially to be commended.

NECROLOGY.

WILLIAM E. WENTWORTH, M.D., aged 24 years and an attending physician of a sanitarium, died from typhoid fever at the Hospital in New Rochelle, New York., Dec. 29, 1897. He was born in Rochester, N. H., where his father is a wealthy farmer.

HENRY PARKE CUSTIS WILSON, M.D., University of Maryland, Baltimore, 1851, died in Baltimore, Md., December 27, aged 70 years. He was a medical writer, inventor of surgical devices and vice-president of the American Gynecological Society. As one of the founders of the Hospital for Women of Maryland he became widely known for his energy and identification with nearly all the hospitals and charitable institutions in Baltimore. He was also a member of the Maryland Academy of Sciences, of the Baltimore Academy of Medicine and of other professional bodies.

ERASTUS C. COY, M.D., University of Vermont, Burlington, 1861, died after a short illness, aged 65 years. He had practiced for twenty-five years at Turner's Falls, Mass., where he died, having joined the Massachusetts Medical Society in 1870, and at a later period the Massachusetts Medico-Legal Society. A widow, a son and a daughter survive him.

DEATHS IN THE PROFESSION ABROAD.—Joachim Voss, M.D., professor of anatomy and medical jurisprudence in the University of Christiana, president and founder of the Association of Norwegian Medical Practitioners and one of the first who performed ovariectomy in Norway, aged 82 years.—Prof. Victor Hüter, for many years lecturer on gynecology in the University of Marburg.—Nikolai Kleinenberg, M.D., professor of comparative anatomy in the University of Palermo, aged 57 years.—M. A. Olivet, M.D., professor of psychiatry in the University of Geneva and author of numerous publications on subjects relating to mental diseases, aged 76 years.—José M. Astigueta, professor in the Medical Faculty of Buenos Ayres, member of the legislature, minister of public instruction, superintendent of the asistencia publica, etc.—Alex. Bykow, M.D., Warsaw, director of the Med.-Chir. Academy.—Braulio Saenz, M.D., a prominent physician and surgeon in Havana, stricken at the operating table.

JAMES F. ARMSTRONG, M. D., Cleveland, Ohio, December 7. Dr. Armstrong was surgeon of the One Hundred and Fiftieth Regiment, Ohio Volunteer Infantry during the war and was later surgeon of the United States Marine Hospital.—J. L. F. Burdich, M.D., Winooski, Vt., December 11, aged 73 years.—Cornelius N. Dorsat, M.D., Montgomery, Ala., December 7, aged 44 years.—William P. Hogue, M.D., Charleston, W. Va., December 7, aged 77 years.—George C. Hoitt, M.D., Manchester, N. H., December 9, aged 62 years.—M. V. B. Johnson, M.D., Sioux City, Iowa, December 9, aged 55 years.—A. W. Peurifoy, M.D., Hanksinsville, Ga., December 10, aged 69 years.—L. S. Sprague, M.D., Williamson, N. Y., aged 78 years.—E. C. Karner, M.D., Mill River, Mass., December 21.—J. W. Mix, M.D., Byron, Ill., December 28, aged 42 years.

COL. JAMES COOPER MCKEE, a retired United States army surgeon, dropped dead at Butler, Pa., December 11, from heart failure. He was born in Butler in 1830 and graduated from the Medical University of Pennsylvania in 1852, commencing practice at Altoona, where he remained four years. In 1858 he was commissioned assistant surgeon in the army and assigned to duty in the West, where he was engaged with different commands until the breaking out of the war. At the second Bull

Run he served as assistant medical director of the army. At the battle of Antietam he was made assistant medical purveyor of the army. He afterward took charge of a hospital at Baltimore, and was next sent to organize a general hospital at Pittsburg. In 1863 Dr. McKee was promoted to the rank of captain and placed in charge of the Lincoln United States Hospital at Washington, D. C., where he remained until the close of the war. During this period 25,000 sick and wounded men passed under his attention. After serving as chief medical officer at Santa Fé, N. M., Fort Wadsworth, N. Y. and Vancouver Barracks, W. T., he was retired in 1891 for injuries received in the line of duty, with the rank of lieutenant colonel, returning to his home at Butler.

JOHN WATERMAN HAMILTON, M.D., Willoughby University, Ohio, 1846, relative of ex-Governor Hamilton of Illinois, and widely known in Ohio, died in Columbus, his home, January 1, aged 72 years. He was a member of the AMERICAN MEDICAL ASSOCIATION and as well of the Ohio State and Central Ohio Medical Societies. His name appears in the list of delegates to the Ninth International Medical Congress, which convened in Washington, D. C., in 1887. He was one of the older surgeons of Columbus and one of its ablest men. He was a descendant of Dr. Wm. Hamilton of Edinburgh, Scotland, who settled in Maryland in 1700 and was the founder of the family in Maryland. Dr. Wm. Hamilton was an able physician and was called in consultation by Dr. Craig in Washington's last illness.

ELTON JOHN SHEROW, M.D., College of Physicians and Surgeons, New York, 1890, died in New York City January 1, aged 24 years. He was an earnest laboratory student, but appears to have overtasked his energies.

PUBLIC HEALTH.

A Quarantine Convention.—The following papers, which have been forwarded to the JOURNAL by Dr. W. H. Sanders of Mobile, Ala., are of interest and self-explanatory. The Doctor says: "The idea is to educate both ourselves and the public, in order that we may reach correct conclusions both as to the theory and practice of quarantine, as justified by the genius and principles of our systems of government, Federal and State. . . . The medical papers are intended to be written, not in technical language, such as would be appropriate before a medical body, but in plain and perspicuous language, such as is adapted to a popular audience. . . . The idea is, further, that each paper shall close by a clear and succinct statement of such propositions as the argument employed seems to justify, which propositions can be submitted to the vote of the convention for adoption, modification or rejection."

THE STATE BOARD OF HEALTH.

MONTGOMERY, ALA., Dec. 7, 1897.

Governor JOSEPH F. JOHNSTON.

Dear Sir:—The recent introduction of yellow fever into one of our Gulf States, and its spread therefrom to several others of them, has strongly emphasized the wisdom of making an effort to devise some more efficient measures than have heretofore existed for the prevention of a similar disaster in the future.

The time seems ripe for such an effort. Our people are deeply and universally aroused on the subject, and justly so, for no subject could be more vitally connected with their social, sanitary, commercial and industrial interests. The magnitude of the questions involved points out the necessity of adopting the wisest course in order to reach the best possible results.

To me it is clear that our first need is light—all the light we can possibly procure. To obtain this, I propose a Quarantine Convention of the South Atlantic and Gulf States. Their geographical position gives them an interest in the subject far above that of any or all of the other States, and their recent experience eminently fits them for dealing with it intelligently and wisely. Their interests are sufficiently homogeneous, and

their exposure to the infection sufficiently great and uniform as to closely unite them in a friendly and earnest effort to formulate systems of protection that shall be founded upon principles of equity and justice and shall at the same time be efficient and harmonious.

At the proposed convention delegates should represent every business and profession, with a view of making a scientific and exhaustive study of both the theory and practice of quarantine. To eminent lawyers should be assigned themes intended to develop and clearly set forth the legal propositions upon which all systems for the protection of the public health should be built. To merchants should be assigned commercial themes, to doctors scientific ones, to railroad and steamboat officials those bearing upon transportation, to editors those appertaining to public policy, to representatives of the postal service those affecting the mails, and to all other classes subjects appropriate to their several departments of business.

With carefully prepared papers on appropriate themes, belonging to each of these departments, together with the discussions that would grow out of them a flood of light would be thrown on the subject of quarantine. In a word, the idea is to make the proposed convention broadly educational, and at the same time to furnish an opportunity for cultivating that spirit of harmony and mutual confidence which will be so conducive to the most judicious legislation.

I deprecate the haste with which many of our people are forming opinions upon the subject of quarantine, and fear they are doing so without due consideration. That our system of quarantine urgently needs to be reformed is freely conceded, but let us by all means search out and apply the best remedies. I know of no other way of finding these remedies than by studying the subject according to the plan briefly indicated.

I have but imperfectly sketched the beneficial results that would flow from a convention of the kind suggested, but I feel sure you will readily see the wide scope of usefulness it would fulfil. I suggest Mobile as the place, and about the first of February next as the time for holding the meeting. Mobile is centrally located with reference to the territory to be represented, and lies on the coast that is most directly interested in securing protection. The hospitality of her people is proverbial, and I feel safe in saying that a body of men meeting there for the purpose indicated would receive hearty and cordial welcome.

May I ask your moral support and co-operation in promoting my objects, feeling sanguine as I do that much may be thereby achieved for the good of the entire country. With distinguished consideration, very respectfully yours,

[Signed] W. H. SANDERS, M.D.,
State Health Officer.

STATE OF ALABAMA. EXECUTIVE DEPARTMENT. OFFICE OF THE GOVERNOR.

MONTGOMERY, ALA., Dec. 8, 1897.

Dr. W. H. SANDERS, State Health Officer.

Dear Sir:—I have just received your favor laying before me your suggestions in regard to calling a Quarantine Convention, composed of delegates representing all classes and pursuits affected by quarantine restrictions, and to consider the origin and most effective means of stamping out epidemics.

I beg to say that I heartily concur with your suggestions. The time seems most opportune for our wisest physicians, lawyers, merchants, farmers and others affected to give thoughtful utterance to sound views. I am sure that such a convention will be a great educational institution: that it will be able to illumine many dark spots, and enable us in the future to enact such wise and wholesome regulations as will properly protect the lives and property of our people. I beg to say that you shall have my hearty co-operation in the matter proposed and that I shall do everything consistent with my position to have Alabama and all the States affected, represented by its best thought in all respect to the vital interests that will be there considered.

Yours respectfully,
[Signed] JOS. F. JOHNSTON, Governor.

PRELIMINARY PROGRAM.—Submitted by W. H. Sanders, M.D., State Health Officer of Alabama.

1. Quarantine with reference to international rights and interests. 2. Federal and State powers as to quarantine. 3. State and National quarantine as affecting commerce. 4. Quarantine as it affects personal rights. 5. Sanitary inspectors of foreign ports. What is being and can be done in this direction. Sanitary conditions of foreign ports that menace us most, and what can be done to improve them. 6. Policing the

sea along the South Atlantic and Gulf Coast to prevent [the] introduction of contagious and infectious diseases. What is being and can be done? 7. National disinfecting stations for ships, where located, how operated, under what rules, with what results and whether others are needed. 8. State maritime disinfecting stations, how many, where located, how operated, under what rules and with what results. 9. Medical inspectors of south Atlantic and Gulf seaports and coast towns. To discover first cases or cases of infectious or contagious diseases, how best to provide for. 10. What steps should be taken in dealing with first case or cases of infectious or contagious diseases that may reach our shores. 11. State and local quarantines, how best to adjust their relations. 12. Depopulation of infected cities, how to be accomplished and to what points may refugees go. 13. Quarantine diseases, what are they and how should they be dealt with? 14. Infection, how conveyed and periods of incubation of infectious diseases. Disinfection, when needed and how applied? 15. The mails and quarantine, how practically to deal with them when proper authority has declared that they should be disinfected. 16. Management of railroad trains during an epidemic of yellow fever, from a railroad standpoint. 17. Classification of freights as to their liability of conveying infection. 18. What may be done to check the spread and to exterminate yellow fever after it has become prevalent in a city? 19. Boards of health, of whom should they be composed and how should they be appointed? To whom should the practical administration of quarantine be committed? 20. Practical difficulties in diagnosing yellow fever. 21. Interstate quarantine from a constitutional, commercial and sanitary point of view. 22. Experiences of a quarantine officer in the recent epidemic. 23. National quarantine. 24. A National Bureau of Public Health. 25. The relation of the press to epidemics and quarantine. 26. Quarantine from a moral standpoint. 27. Sins and absurdities committed in the name of quarantine in the recent epidemic. 28. Introduction of yellow fever into the country in the past; from what places introduced and how.

Typhoid Fever Epidemic in New Jersey—A serious epidemic of fever has befallen Paterson, N. J. It began at an orphan-asylum and thence spread to other parts of the city. About seventy cases are known to have existed. It is the belief of those who have investigated the matter, that the cases at the institution and in various private families originated from the milk supplied by a certain dairyman, in whose family there had been three cases of fever. These patients had been sick for a month or more, with what was called "remittent fever," and their discharges found their way into the water that was used for washing milk cans and other appurtenances of the dairy. Among the other towns where typhoid fever prevails to a greater or less extent are Passaic, Arlington and Kearney. A boycott against New Jersey milk has resulted, not only in New York City, but in certain of the large cities of the former State. Thousands of quarts of milk are being rejected every day, and are sent back to the shipping point, compelling the farmers to rush them off to the local creameries, which are now glutted and refuse to take any more, so that the daily product on many of the farms is a dead loss. Many dairymen who personally fought in its effort to secure legislation that would have averted such a calamity are now willing to co-operate in securing some stringent laws that will prevent a recurrence. The fact that they are losing thousands of dollars a day has brought them to their senses, and as many of them are innocently suffering they are willing that some laws should be obtained that will bring about an immediate supervision of dairies by the boards of health. Upward of fifty epidemics with a long list of fatalities have been caused in New Jersey in recent years by infected milk, and invariably by fevers in the families of those handling and dispensing the same to a large number of consumers. Until the epidemic has become alarming, there is no official investigation, and then it is found that some dairyman is selling milk with a bad case of fever in his house, with the water that he uses to cleanse his dairy utensils infected. The authorities then try to stop him from dispensing any more milk, but the damage has been done, as the long list of the sick and the dead will show. A stringent law is needed which will compel local boards of health to exercise the same precau-

tion as the board of health in the cities and towns. There is no attempt made at reporting infectious diseases, for the reason that the township board of health would take no action if they were reported. If the physician who finds fever in a country farmhouse, where the principal business of the occupants is preparing milk for the market, would report the case to the local board of health as soon as the fever makes its appearance, and the township board of health would report to the State Board of Health, that creamery would be seized at once and communication shut off with the consumers of the milk.

Volunteer Organizations for the Detection of Plumbing Defects.—For several years Edinburgh has had its unofficial system for the expert sanitary examination of dwellings. There is now in New York City, a somewhat similar undertaking, under the name of the Building and Sanitary Inspection Company, and they "offer their services to those who live in houses, for the discovery and correction of causes of unhealthfulness in the appointments and environment of the dwelling." A few years ago one of the most aristocratic apartment houses in the neighborhood of Central Park experienced an invasion of diphtheria, and though there were several victims in different rooms, the evidence was nearly conclusive, that it had originated in the house; and one bereaved father called in a sanitary engineer, in spite of the protests of the indignant owner who told of how much money he had spent on his ornamental bathtubs and nickel-plated pipes. The expert found that the ventilating pipe that should have gone out at the roof, and extended above it, left off at the lower side of the ceiling of the upper story and was there replaced by a painted cylinder of wood, which passed up through the storage attic. The noisome exhalations could do nothing else than diffuse themselves throughout the house, and the outraged inmates took the matter to court, where there was a preliminary hearing: and rumor had it that the murderous owner of the building paid fabulous sums to "buy off" his tenants, and immediately had the most faultless of plumbing put in under the direction and inspection of a competent sanitary engineer. This could not recall to life the dead; and with variations the above is a story that is repeated again and again every year, and tenants and owners are very active after the mischief is done. Had the people who suffered from this landlord's cupidity caused an examination to be made before they rented their rooms, a wholly different result would have been seen. Is it possible that careful fathers who are good business men in other matters, can have been inveigled into attempting to live in houses where eighty in a hundred are defective in the vital point of healthfulness. They were not inveigled, they were simply satisfied with their own judgment, or took on trust the assurances of agents or owners. Many houses were carefully plumbed according to the lights of the time when they were built: but in some the plumbing is worn out, and when a replacement is suggested there is a distinct painful thrill in the pocket nerve of the owner, and he fights it off as long as possible: and where he suspects that there should be a thorough overhauling, but the prospective tenant does not push his inquiries, he soothes his conscience by the thought that "the sanitary condition of a house is, after all, a matter of concern only to the people who live in it." But if neglect is proven and taken to the courts, he wishes he had not waited to be forced to do right. There has arisen in some quarters a tendency to ridicule the idea that the germs of disease are to be found in the emanation from defective pipes, and though there is, no doubt, a degree of high health and robust constitution that can resist their action, there are thousands who suffer from what for lack of a more definite classification, they call "malaria."

"Light from Dust."—A plant at Shoreditch, London, in which Lord Kelvin is interested, has recently been opened, the object of which is to destroy waste and at the same time utilize it for

the production of electricity for lighting purposes. It is probably the first of its kind on anything more than an experimental scale; and this has been done in a large borough of 130,000 persons, mostly belonging to the working class. The steam requirements of the electric lighting station, great though they be, must be regarded of secondary importance in comparison to the hygienic manipulation of the refuse compared to the doubly expensive method of sending it away by rail or barge to be utilized for raising some low-lying land on which in a few years houses would be built. Not only will the cost of getting rid of the dust be materially reduced to the parishioners, but the districts where it was "shot" will benefit largely by its absence. Medical men in localities where town refuse has been deposited have been impressed that its presence is a determining factor in the production of diphtheria. From a health point of view the introduction of electric lighting and electric power can only be regarded as a distinct advance. It is unnecessary, in this year of all others, to dilate on the benefit of the electric light over other methods of lighting, but in Shoreditch special arrangements have been made such as in the introduction of the "penny-in-slot" meter principle, and otherwise, to bring the light within the reach of the small shopkeeper and householder. Further, the use of electric energy is certain to be largely appreciated in the numerous small factories and domestic workshops with which the district abounds. It is not necessary here to enter into a description of the various works comprised in the undertaking, but reference must be made to one or two of the novel features which have here been combined. By the system of feed thermal storage which is brought into operation for the first time, the steam generated during the daytime in the boilers is passed into a thermal storage cylinder, where it is mixed with a small quantity of cold water from the feed-pumps, the proportions being such that, when the evening approaches, the cylinder is full of water at the temperature and pressure of the steam required by the engines. The cylinder is then shut off from the feed pumps and connected to the boilers, which in their turn are connected direct to the engines; hence, when the boilers require feed-water, they are supplied with it from the cylinder at such a temperature that the fuel which is then being burnt has merely to furnish to the water in the boiler the heat sufficient to overcome the latent heat of evaporation at the required pressure. The result of this arrangement is that the boilers are able to evaporate about one-third more steam than they would be able to evaporate were they connected directly with the water-mains; and, moreover, the importance of the thermal storage cylinder is further enhanced by the fact that it acts as a water purifier. The six boilers are all fired with the waste gases from two destructor cells, one on each side of the boiler. The products of combustion from the destructor cells are led under the boiler tubes immediately above the level of the fire-bars, the latter being fitted in the boiler together with fire-doors, in the same manner as if the boiler were fired with coal, irrespective of the dust destructor cells. This grate is provided for the express purpose of enabling the boilers to be fired by coal alternatively or simultaneously with the absorption of heat from the waste gases of the destructor cells passing through the boilers. This arrangement fulfils a two-fold object. 1. The provisions of the secondary fire before referred to, which is in the most desirable position for further heating the destructor gases immediately they enter under the boiler, should that operation be requisite, and having further advantage that the heat so produced is ultimately so completely absorbed by the boiler, and thus turned into profitable use. 2. The arrangement adds to the steam-raising power of the boilers when the heat of the destructor gases is not sufficient to produce all the steam required, or when the destructor cells attached to a particular boiler are out of order, to enable the boiler to be entirely fired by coal or coke. It has been found, however, that the heat produced by the destruction of the "dust" is sufficient without the addition of any coal. There are twelve cells in all in the destructor house, which measures eighty feet square. In place of the more usual inclined road and tipping platform considerable saving is effected, both in space required and in horse

flesh, by the introduction of a series of electric lifts and motor cars for revising and distributing the refuse throughout the cells. One man is thus able to keep the whole twelve cells charged at regular intervals, and the refuse is never left to ferment or heat on hot brickwork or ironwork, and so prove a nuisance to the neighborhood. A like result from the gases which might escape is prevented by the use of fans which ventilate the building and at the same time drive the air through the furnaces. A connection has also been made from the adjoining sewer to the intake of one fan, which constitutes an experimental effort to ventilate the sewer by passing the gases abstracted therefrom through the fires, and thus rendering them innocuous.—*Sanitary Journal*.

MISCELLANY.

Prince Bismarck.—A recent cable dispatch states that Prince Bismarck is suffering from some form of dropsy, and has recently had his feet tapped.

Erratum.—In the *JOURNAL* of December 4, page 1184, second column, line 8, the name of the author of the article on rheumatism should read Dr. Edmund L. Gros instead of Geos.

Parke, Davis and Co., have issued a handsome little brochure, the "Lofoten Islands and their principal product," in which the pictures of this group of islands are beautiful and of general interest.

The Russian Census.—The revised returns of the Russian census gives the total population of that country at 129,000,000. This makes Russia third in rank among nations, China coming first with an estimated population of 490,000,000 and the British Empire next with 208,000,000.

A Book by Dr. Outten.—Dr. Warren B. Outten, Chief Surgeon of the Missouri Pacific Railway, has written a book: "Man's Inherited Martyrdom—A Fitful Study of Degeneration." The work is of the greatest interest and is sure of a favorable reception. It will be printed as a serial in the *Tri-State Medical Journal and Practitioner*, of St. Louis, which has the exclusive right to the publication.

The Passing of the Family Doctor.—The London *Lancet* has lately expressed its regret at the signs of the wasting prestige and influence of the medical profession. That looks as if the embarrassments that beset physicians in New York were operating in London also. There seems to be some reason to anticipate a time when New York families will contract with a syndicate of physicians, comprising a complete set of the necessary specialists for the supervision of the family health at a fixed annual price.—E. S. Martin in *Harper's Weekly*, Dec. 25.

Missed Everything Except Vaccination.—An old Georgia darkey, with his arm in a sling, was talking to another on a West End car yesterday. "Yes, suh?" he said with emphasis. "I gone up now, fur sho! You see dis arm in de sling, don't you?" "Yes." "Well, suh," the old man continued by way of explanation, "I'll be 80 years old next harvest; I done see lots er trouble in my day, but by de grace er God I miss de Ku-Klux, I miss de Vigilance Committee, I miss de White caps, en I miss de Regulators, but now in my old age, please God, waxinators kotched en cut me."—*Atlanta Constitution*.

Ocular Hemorrhages in Young Subjects and in Adults.—Abadie, in the *Soc. d'Ophthal. de Paris*, lays stress on two symptoms which he thinks are of importance as bearing on the causation of intra-ocular hemorrhages in young subjects: 1. The epistaxis which often precedes or accompanies them. 2. A noticeable diminution in the number of the red corpuscles in the blood. These seem to indicate that the hemorrhagic process depends on an alteration in the blood. The results of treatment directed to improving its quality have been found by Abadie to be most satisfactory. He strongly recommends a glass of sulphuric lemonade, extract of cinchona 1 gram, and perchlorid of iron 10 to 20 drops, to be taken daily. To favor

absorption of the effusion he applies the artificial leech to the temple. Hemorrhages associated with choroido-retinitis are not to be confused with the above, and require a mercurial treatment.—*British Medical Journal*.

Antivivisection Bill. The following authoritative statement from Senator Gallinger appears in the *Congressional Record*. "Upon solicitation from several Senators saying that they were receiving letters from constituents, protesting against the passage of the Bill, I allowed it to drift along and did not ask for the consideration of it. On May 13, 1897, the Bill was again reported and is on the calendar. . . . At an early date I shall move to take up that Bill, which is Senate Bill 1063, Calendar No. 136. I trust that when I ask the consideration of the Bill it may not be objected to, but that that matter which to my mind is extremely important, and a controverted matter, I will say, on the part of physicians, scientists and humanitarians, may have a fair discussion and that we may have a vote of the Senate deciding whether or not that Bill shall pass this body."

Reading Through Opaque Substances.—Professor Grasset reports a curious experience with a subject who was able to read the contents of a letter enclosed in silver paper inside a sealed envelope at 300 meters distant. No one in the town knew the contents of the letter, which had been sent especially for the test. The affair was reported to the Academy of Sciences of Montpellier, and the still sealed letter presented, which was opened and found intact, although a pin had been passed through it and buried in the seal. The contents were an unfamiliar French verse which was read correctly, and a Russian, German and Greek word which the subject asserted she could not read, concluding with the correct date and signature. A committee has been appointed to go to Narbonne and make still further tests of Dr. Ferroul's "subject" in the interest of science.—*Scmaine Méd.*, No. 56.

Causes of Poverty.—In Europe paupers are defined to be those who receive aid from government or charitable funds. The proportion of paupers to the whole population is highest in England, 28 per 1,000. In Scotland it is 24, in Ireland 23, in Holland 20, in Italy 10, in Austria 9, in France 8 and in Germany 7. There is no similar division made officially in the United States, and, taking the country through, the proportion here is less probably than 2 per 1,000. When it comes, however, to the causes of poverty, the American statisticians are, so to speak, right in line with what some persons would call their conjectures, but what they describe as their conclusions. Thus, of 100 cases of poverty, 11 per cent. are chargeable to drink in excess, 21.3 per cent. to what the statisticians call "misconduct," a rather vague designation for unwise or reprehensible acts; 28.5 per cent. to lack of work or inadequate pay for work done, or insufficient, half time employment; and most of the remainder to "misfortune."—*New York Sun*.

The Restoral of Flogging as a Legal Punishment Recommended. The *Lancet* is more than half right in its advice to have flogging made a part of the punishment for toughs who throw stones at railway trains. The custom of throwing stones at trains is far too common and in addition to its being almost impossible to arrest those who do such things, the penalty provided by law is far too light. A peculiarly sad accident arising from this habit was reported in the *Daily Press* on October 19 as follows: "Ben Hitchen, a well-known express driver on the North Western Railway, lies at Crewe unconscious. He had charge of the Scotch Express to Carlisle, and when passing under Hartford bridge, going at great speed, a stone hurled with much violence from the bridge struck him over the eye, inflicting a fearful wound. Erysipelas has set in, and his condition is precarious." Drivers of express trains are exposed to quite enough dangers from the nature of their ordinary work without having to undergo such risk as the one mentioned above. If the scoundrel who threw the stone is

ever caught, though we are much afraid he will not be, he deserves the soundest flogging that a criminal ever had. In a case like this one not only is the driver's life imperiled, but the lives of all those in the train. We sincerely hope that the law may be amended so as to make it legal that anyone who either throws any missile at a train, whether he hit it or not, or places an obstacle in the way of a train should be well flogged or birched in addition to a term of imprisonment.

Degenerate Females at the Guldensuppe Murder Trials, New York.

- During the revolting recital of testimony in the Thorn murder trial there were numerous women present who seemed to delight in listening to the shocking, disgusting details of the butchering of Guldensuppe. It is difficult to believe that any woman not morally and physically a degenerate would seek to be present at such a place during such a scene. Yet at Thorn's trial some of these creatures fought with each other in the corridors in their desire to crowd into the court room. In the "cause of common decency, in the name of womanhood, which these curious females dishonor, the Bench should use its utmost endeavors to keep out the unwomanly women of morbid appetites. Under shelter of constitutional rights, never intended to be used for base purposes, they may seek to gain admittance, but the judges should do all in their power to drive them out of the trial room. And wardens of prisons should close the door against them when, later, these queer human beings in petticoats come with their floral offerings and their sickly sentimentality to visit convicted murderers in their cells.

-*New York Herald.*

Water-Supply and Irrigation Papers. The following numbers of the series of Water Supply and Irrigation Papers have been printed and can now be had on application, or until the supply of each is exhausted. Requests specifying certain papers and stating reasons for asking for them are given prompt attention, but it is impossible to comply with general demands for all of the series indiscriminately: 1. Pumping Water for Irrigation, by Herbert M. Wilson, 1896, 80, 57 pp. 2. Irrigation near Phoenix, Arizona, by Arthur P. Davis, 1897, 80, 97 pp. 3. Sewage Irrigation, by George W. Rafter, 1897, 80, 100 pp. 4. A Reconnaissance in Southeastern Washington, by Israel Cook Russell, 1897, 80, 97 pages. 5. Irrigation Practice on the Great Plains, by Elias Branson Cowgill, 1897, 80, 39 p. 6. Underground Waters of Southwestern Kansas, by Erasmus Haworth, 1897, 80, 65 pp. 7. Seepage Waters of Northern Utah, by Samuel Fortier, 1897, 80, 50 pp. 8. Windmills for Irrigation, by E. C. Murphy, 1897, 80, 49 pp. 9. Irrigation near Greeley, Colo., by David Boyd, 1897, 80, 90 pp. 10. Irrigation in Mesilla Valley, N. M., by F. C. Barker (*in preparation*). (Other papers on related subjects.) F. H. NEWELL, Hydrographer in Charge Washington, D. C., Oct. 15, 1897.

Rush Medical College Changes. Prof. Edward L. Holmes, president of Rush Medical College, has resigned. A meeting of the faculty was held January 4 for the purpose of considering the resignation of Dr. Holmes and for passing on the question of affiliation with the University of Chicago. On the question of joining with the University every member present voted in the affirmative. The resignation of Dr. Holmes was also accepted. The retiring president of Rush Medical College, Dr. Edward L. Holmes, will be 70 years of age February 11, and his resignation is to take effect at that time. More than a year ago he announced that when he was 70 years of age he would retire from the presidency to make room for some younger man. He asserts that his age is the only reason for resigning. He was the first physician in Chicago to limit his practice to diseases of the eye and ear. He was the founder of the Illinois Eye and Ear Dispensary at the close of the war. He was prompted to do so by the large number of returning soldiers who were suffering from affections of the eye resulting from the hardships of the field. He became a professor in

Rush Medical College in 1860 and in 1883 was made its president. When the Presbyterian Hospital was founded in the latter year he was one of the doctors effectively interested in the undertaking. For more than a year Dr. Holmes has been in feeble health. Rush Medical College lacks only three years of being as old as incorporated Chicago. It was founded in 1836. It has the oldest charter of any school in the State. In 1843 the school was at 49 Clark Street and it had twenty-two students. The next year it was removed to Dearborn Avenue and Indiana Street. The home of the school was destroyed in the great fire of 1871 and five years later a structure was erected for it on the site of the buildings it now occupies at Harrison and Wood Streets.

Detroit.

AT THE regular meeting of the Wayne County Medical Society, December 16, Dr. C. D. Aaron presented a paper entitled, "The Diagnostic Value of Transillumination of the Stomach." The author exhibited a number of life-size diagrams representing the healthy stomach in its normal position as it appears when the interior is illuminated by the gastrodia-phane and several pathologic conditions of the organ, such as dilatation, carcinoma of the pylorus and of the body of the stomach, gastroptosis, etc. The author then gave a description of and exhibited the instrument known as the gastrodia-phane, and illustrated its practical uses by an actual introduction before the Society into a patient's stomach, showing by transillumination the dilated condition of the organ. In the discussion that followed the author stated that the patient's condition was undoubtedly due to repeated stomach washings and strongly condemned its general practice by the profession.

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION at its regular meeting, December 20, listened to an interesting paper by Dr. A. N. Collins, entitled "How Shall We Treat Threatened Puerperal Convulsions?" in which the doctor said that a thorough knowledge of the cause or causes of puerperal convulsions would greatly aid in prophylaxis and treatment. The Doctor took up the pathology of the subject, giving the different theories advanced as to the cause of puerperal convulsions. He said: "I believe a majority of us hold the broad idea that the poisons developed in the tissue metabolism of physiologic cell activity imperfectly eliminated by the excretory organs, accumulate in the system, from which we get eclampsia or convulsions." In those dying from the disease, he continued, the kidneys are found in all conditions from the normal to acute degenerations, dilatation of the pelves and ureters, and also chronic nephritis. It has been found that the cerebral arteries have been involved even in young women; or again, another theory is that a toxic substance is produced in some unknown way which causes contraction of the arteries, arterial degeneration, acute degeneration of the kidneys and acute nephritis and that this poison is the cause of the convulsions and the cerebral and vascular phenomena. In all theories a quantitative and qualitative examination of the urine is our guide to the condition of our patient and ought to tell us when we need to interfere in some way to save our patient. The Doctor then gave the table as published by Prutz, from which he summed up that steamings, sweatings, morphia, veratrum viride, bromids, bleedings and other remedies were of little avail and showed conclusively that prophylaxis was what was needed. The Doctor further said that those cases in whose urine traces of albumin are found and who are near full term, are not to be considered serious, but those who show albumin in the early part of their pregnancies, and especially when the albumin increases in quantity and the urine decreases, are grave. The Doctor also placed considerable stress upon "flashes of light," irritability of the vascular system, rapid and wiry pulse together with an increasing anemia. For this latter condition the Doctor recommended first an abundance of water, then a milk diet, saline cathartics, acetate of potash, digitalis, hot

baths and proper hygienic surroundings, efforts being made to carry the same beyond the seventh month; then if the conditions were not better, to evacuate the uterus. The Doctor then told how he would bring on labor: First give a bichlorid douche, then a sterilized catheter should be passed into the womb between the uterine wall and amniotic sac, tamponed and left. The Doctor tries to prevent the sac from rupturing, as he thinks this materially aids in dilating the os uteri and makes the labor more regular and natural. If the convulsions should begin, then the sac should be ruptured to relieve pressure. The Doctor then gave the record of two cases in which both mother and children were saved.

HEALTH REPORT for the week ending December 24: Births, 42; deaths, 46. Contagious diseases: Diphtheria, 10; scarlet fever, 35; 1 death from diphtheria; none from scarlet fever.

Denver.

THE WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. The seventh annual meeting of the association held in this city on December 29 was a success in every respect. The members from outside of Denver who represented the States of Missouri, Kansas, Iowa, Indiana, Utah and Nebraska were delighted to find the brightest of suns over their heads from dawn until evening twilight, and they had no use for the heavy overcoats with which they had provided themselves. Five sessions were held, morning, afternoon and evening on the first day, and morning and afternoon on the second day. The attendance at all sessions was good. Almost all physicians residing in Denver and in the neighboring cities availed themselves of the opportunity and attended one or more sessions. Especially large was the attendance in the evening of the first day when the members of the Denver and Arapahoe Medical Society courteously omitting their stated meeting have joined the session in a body. In the evening of the second day a banquet was tendered the visitors by the Denver physicians, and seventy Æsculapians sat to the table and whiled away the time in intercourse and discourse until a late hour. Dr. H. G. Wetherill responded to the toast "our guests." The guests in parting did not bid adieu to the Denverians, but *au revoir* at the meeting of the AMERICAN MEDICAL ASSOCIATION in June, 1898.

STATISTICS OF MEDICAL LIBRARIES. At the last stated meeting of the Denver and Arapahoe Medical Society it was resolved that the pamphlet entitled "How Every City may Secure a Medical Library," written by the secretary of the Society, Dr. C. D. Spivak, should be mailed to every county medical society in the United States. The committee appointed for that purpose have issued a circular, which may be obtained from Dr. C. D. Spivak, Denver. The plan as outlined in Dr. Spivak's pamphlet is a very simple one. Suppose there is a city in which, say, thirty or forty Æsculapians dwell in peace and harmony. Every one of them has a library which is composed of books, periodicals, reference works, etc. There are however no two private libraries in which all the books are alike. Now, in order to make all the books available to each and every physician residing in that community, it is only necessary to take the largest private library in the city as a foundation and prepare a careful card catalogue of all the books therein. Then go over all the other private libraries and add such books as are not found in the first. Thus, when all the libraries are gone over, and *all* the books are entered, the catalogue is placed in the public library or in any other place for reference. Of course the card bears the name of the owner, of whom one may obtain the book. As the circular states, this plan was adopted here in Denver and works with great success.

THE COLORADO MEDICAL LIBRARY ASSOCIATION. The fourth number of the *Monthly Bulletin* of the Colorado Medical Library Association is out. As far as bibliography of medical libraries is concerned, this bulletin is a unique production, probably the first and the only one ever published in the United States. In the succeeding issues, the editor promises to devote considerable space to the general question of medical libraries in the United States. The bulletin will be sent gratis to all medical libraries by addressing Dr. Henry Sewall, 23 18th Avenue, Denver, Colo.

DENVER CLINICAL AND PATHOLOGICAL SOCIETY.—The December meeting of the Society was held in the offices of Drs. Cover, Fleming and Leroy. Dr. Wetherill reported the use of a double drainage tube devised by himself for draining and flushing pelvic abscesses through the vault of the vagina. Dr. Parkhill reported and exhibited a case of ununited fracture of the tibia and patella in which his clamp was used with complete success. Dr. Block spoke of the absolute necessity of asepsis in the removal of foreign bodies from the cornea. He also reported the use of the drug called phiosenamine for use in softening and absorbing corneal scars and all adventitious tissue in any part of the body. Dr. Waxham exhibited a polypus which had completely obstructed one nasal cavity and caused considerable distress to the patient. He also reported a case of croup in an adult 40 years old. Dr. Hershey reported a case of hemoptysis occurring periodically without any relation to menstruation. The attacks are usually preceded by the enlargement of the spleen and liver. Examination of the blood negative. Dr. Lyman reported a case and exhibited specimen, wherein a tumor appeared under the annular ligament of the right wrist following a sprain two years ago. Upon operation the tumor was found to contain a gelatinous fluid, rice bodies and a piece of tendon.

ST. ANTHONY'S HOSPITAL. At the annual meeting of the executive committee of the staff of the hospital the following staff was appointed for the year: Surgery: Attending, Drs. John Boice, Leonard Freeman and J. W. Neil. Medicine: Consulting, Drs. E. P. Hershey, P. D. Rothwell, C. P. Burns; consulting, Drs. John Elsner, J. N. Hall, R. B. Freeman and C. P. Conroy. Gynecology and abdominal surgery: Attending, Drs. C. K. Fleming, T. H. Hawkins. Neurology: Attending, Drs. J. W. Rothwell, S. D. Hopkins. Pediatrics: Attending, Drs. C. F. Shallenberger, J. W. Ryan. Ophthalmology and otology: Attending, Drs. R. E. Lemond, D. H. Coover. Obstetrics: Consultant, Dr. W. H. Buchtel; attendant, Drs. T. M. Burns, C. P. Van Zant. Laryngology: Attendant, Dr. Robert Levy. Dermatology: Drs. W. H. Davis and J. M. Blaine.

THE HEALTH OF THE CITY. The total number of deaths for the month of November was 137, representing a rate of 10.28 per 1,000 per year; there were thirty less than in October. Scarlet fever mortality, 3 in 48 reported cases; diphtheria, 9 in 45 cases; typhoid fever, 6 in 36 cases. Number of days with 0.91 inch or more of rainfall, 4; mean barometer, 24.72.

Washington.

CHILDREN'S HOSPITAL.—Dr. J. William Hart has been appointed resident physician of the Children's Hospital, having successfully passed the competitive examination for the position.

THE WASHINGTON DENTAL SOCIETY.—The Washington City Dental Society has elected the following officers for the ensuing year: W. N. Cogan, president; Charles W. Appler, vice-president; W. R. Talbott, secretary; M. F. Finley, treasurer; H. B. Noble, librarian; J. H. P. Benson, essayist.

MEDICAL RULES FOR THE POLICE. Commissioner Wight is having the police manual amended by the addition of rules to the police regulating their management of the sick and wounded found on the streets. The special instruction refers to the immediate care of persons to be removed to hospitals, who have been shot, cut or otherwise wounded, drowned or overcome by heat. Such rules and instructions have been needed in Washington for a long time.

NEW RULES OF THE HEALTH OFFICER. Health Officer Woodward has issued an order prohibiting any member of his force from entering bar-rooms and like places, while on or off duty except when required to do so officially. They are also prohibited from swearing, at least while on duty. They are also prohibited from making any unfavorable criticisms of any department of the United States or District Government. All their reports in future are to be considered confidential.

THE WASHINGTON TRAINING SCHOOL FOR NURSES.—The Washington Training School has been reincorporated. The medical members of the incorporation are Drs. G. N. Acker

H. L. E. Johnson and D. Percy Hickling. The school, which has been closed, will shortly be in operation on new and improved plans.

PROVIDENCE HOSPITAL IN COURT.—The Providence Hospital, which has recently come to the help of suffering humanity in the District, by the erection of a building on its grounds for the care of minor contagious diseases, is being opposed through the courts, on the ground of the sectarian character of the incorporation, it being alleged that the appropriation of public money for the support of any religious society is a violation of the constitution of the United States. The treasurer of the United States, through the district attorney, has appeared before the circuit court and made argument in favor of the Hospital and the matter has been taken under advisement by the judge.

MEDICAL CHARITY ABUSES.—The Standing Committee of the Medical Association of the District of Columbia at its recent meeting notified officially the medical staffs of the hospitals and dispensaries of the District that they must endorse and comply with the recent regulations adopted by the Association on the subject of medical abuses, and make their reply to the Association not later than January 1. It is believed that the medical staffs are a unit in agreeing to these matters, but some opposition may be expected from the lay members of the different boards. The Standing Committee and the Association, however, have taken a positive stand that the rules and regulations shall be rigidly enforced, and violators promptly disciplined.

Louisville.

APPOINTMENTS.—At a recent meeting of the Board of Public Safety recently appointed by the new mayor the following appointments were made, they being subsequently approved by the Mayor and Common Council: Health Officer, Dr. M. K. Allen; Superintendent of City Hospital, Dr. P. S. C. Barbour; City Physicians, Drs. J. W. Guest and Brent Palmer. Dr. W. P. White was removed to make a place for Dr. Allen. Added to the endorsements of Dr. White already given was that of the State Board of Health, which, while in session in the city, called in a body on the mayor and the board and requested that Dr. White be retained. Dr. Barbour was retained as Superintendent of the City Hospital, in which capacity he has ably served for seven years. Fifty applications were on file for the position of city physician, which pays \$75 per month. Dr. Palmer, one of the successful applicants, is a son of the late Dr. E. R. Palmer, whose sad death several years ago will be recalled by many.

SPRING AND SUMMER SCHOOLS.—On January 1, the Hospital College of Medicine and the Kentucky School of Medicine begin their annual session, this being the first year of the Kentucky School existing as the Medical Department of Kentucky University.

RODMAN.—Dr. W. L. Rodman having completed his course of lectures at the Medical Chirurgical College of Philadelphia, has returned to Louisville in time to begin his work in the Kentucky School.

Cincinnati.

THE PUBLIC LIBRARY will hereafter refuse to supply books to persons living in houses where contagious diseases exist, and books being returned from such houses are to be disinfected or fumigated before being returned to the shelves of the library.

THE TRUSTEES OF THE MASSILON STATE INSANE HOSPITAL have asked for an additional appropriation of \$25,000 to furnish the buildings about completed. Of the \$434,218.91 already appropriated, \$365,124.75 has been spent. When completed it is estimated that it will cost about \$200,000 a year to run the institution.

THE MORTALITY REPORT for the week shows: Zymotic diseases, 9; phthisis pulmonalis, 16; other constitutional, 8; local, 57; developmental, 8; violence, 5; total from all causes, 102; still births, 11; under five years, 21; under one year, 12; preceding week, 104; corresponding week 1896, 117; 1895, 117; 1891, 121; annual rate per thousand, 13.09.

Societies.

The following meetings are noted:

California.—Annual of the Los Angeles County Medical Society, Los Angeles, December 17.

Indiana.—Delaware District Medical Society, Hartford City, December 21. Mitchell District Medical Society, West Baden Springs, December 27-29. The State Pediatric Society was organized December 28 at Denison.

Iowa.—Central District Medical Society, Jewell, December 21.

Minnesota.—Ramsey County Medical Society, St. Paul, December 27.

Missouri.—Kansas City Academy of Medicine, January 11.

Nebraska.—Elkhorn Valley Medical Society, Norfolk, January 4.

Ohio.—Utica Medical Society, December 30.

South Carolina.—Laurens County Medical Society, Laurens, December 30.

Texas.—South Texas Medical Association, Beaumont, December 28 and 29.

Virginia.—Academy of Medicine and Surgery, Richmond, December 21.

Wisconsin.—Central Wisconsin Medical Society, Beloit, December 28.

CHANGE OF ADDRESS.

Block, G. M., from Steele Block to the Denison Building, Denver, Colo.
Boyer, E. N., from 601½ Hamp St. to 227½ S. 7th St., Quincy, Ill.
Frink, L. J., from Bartlett to Nashua, N. H.
Heller, Chas., from 7114 Cottage Grove Ave. to 4012 Ellis Ave., Chicago, Ill.

Lemen, H. A., from Baltimore, N. C., to Augusta, Ga.
Matheson, J. S., from Chicago to Brandon, Manitoba, Canada.
W. F. McNutt, from Sutter and Montgomery to 1220 Sutter St., San Francisco, Cal.

Parker, D. L., from 559 to 835 Jefferson Ave., Detroit, Mich.
Sargent, A., from Hopkinsville to Frankfort, Ky.
Smith, J. W., from 2313 Washington St. to 2160 Market St., St. Louis, Mo.

LETTERS RECEIVED.

ORIGINAL ARTICLES.

WHAT ARE THE CHARACTERISTICS OF A TRUE CARDIAC TONIC? AND WHAT ARE THE PHYSIOLOGIC DIFFER- ENCES BETWEEN A TONIC AND A STIMULANT?

Presented to the Section on Physiology and Dietetics, at the Forty-
eighth Annual Meeting of the American Medical Association,
at Philadelphia, Pa., June 1-4, 1897.

BY N. S. DAVIS, M.D.

CHICAGO, ILL.

That all morbid conditions, both of function and structure, are deviations from the normal or physiologic conditions of living matter, probably no thoughtful physician will deny. If the proposition is true, then the basis for the study of disease is a correct knowledge of the actual physiology of all parts of the living body.

The more accurate and complete our knowledge of the structure and function of any given part, and its natural relations to all the other parts of a living body, the more readily we can appreciate all deviations from the physiologic standard of action or condition so far as to constitute disease.

If a correct knowledge of the natural or healthy structure and functions of any given living part is the proper basis for studying the departures from that standard of health which may constitute disease, it is equally true that the same knowledge must constitute our basis for determining the action of all medicinal agents. Therefore, if we would clearly appreciate the important characteristics of a true cardiac tonic we must first comprehend the complete natural mechanism and functions of the heart and its physiologic relations to all other parts of the living body of which it is a part.

All lexicographers agree that a *tonic* in medicine is an agent or medicine that is capable of "increasing the strength and vigor of the animal system;" or, as I would prefer to express it, an agent or medicine capable of *increasing the natural functions* of a part or of the whole of the living body. The natural structure of the heart is chiefly muscular, supplied with blood vessels, and apparently three varieties of nerves; and its physiologic function is to aid in the circulation of the blood. Such aid is rendered by the regular rhythmic contraction and relaxation of the muscular structure of the heart by which its cavities are successively filled and emptied in given time and with given degree of force. And it might be claimed that the essential quality or characteristic of a cardiac tonic is such an agent or medicine as would increase the tone and efficiency of the muscular contractions without unduly increasing their frequency. But both clinical and experimental observations have clearly shown that the co-operation of four conditions are

essential for maintaining the full normal efficiency of the heart in aiding the circulation of the blood. These conditions are: 1, the natural tone or contractibility of the cardiac muscular structure; 2, the presence of healthy blood or some albuminous fluid of similar composition; 3, the natural sensibility of the three sets of nerves co-operating in regulating the muscular contractions and relaxations of the heart; and 4, the presence of a due proportion of oxygen in the arterial blood or the fluid supplying the left cavities of the heart. If the co-existence of all these conditions is necessary to the continued efficiency of the function of the heart in circulating the blood, it must be apparent that the characteristics of every true cardiac tonic must be both positive and negative. That is, they must be capable of positively sustaining or increasing the efficiency of the cardiac muscular contraction and the sensibility of the several nervous structures, while negatively they must not so alter the constituents of the blood as to impair their oxygen receiving and distributing capacity, nor impair the depth and efficiency of respiration by lessening the sensibility of the respiratory nerve centers, nor so far lessen the sensibility of the inhibitor nerves of the heart as to allow the cardiac contractions to become too rapid or irregular. For any agent that increases the frequency of the cardiac contractions above the natural standard, necessarily leaves less time for the ventricles to fill in diastole, and consequently less blood is sent out by each systolic action and correspondingly less efficiency is given to the whole circulation. This is illustrated in exophthalmic goiter and in all those diseases characterized by marked frequency of cardiac action, and by cutting the vagus or inhibitor nerves of the heart in animals. And this leads us to the exact physiologic differences between a cardiac tonic and a cardiac stimulant. The first increases the tone of the cardiac muscles and the efficiency of their contractions without increasing their frequency beyond the normal; but the latter simply increases the excitability and frequency of cardiac action without necessarily increasing either its force or efficiency. And yet, throughout the greater part of our medical literature, the words tonic and stimulant are often used interchangeably or as synonyms, and nowhere more frequently than in reference to remedies for influencing the heart.

Perhaps no other physiologic fact has been more completely established than that both nerve sensibility and muscular contractibility in living animals are directly dependent upon the presence of oxygen in the blood or fluid circulating in the vessels. Consequently, the continuous oxygenation and decarbonization of the blood is not only essential to the continuance of life, but any diminution of the process below the physiologic or natural standard of health lessens both nerve sensibility and muscular contractile force.

Hence it was stated as one of the characteristics of

a cardiac tonic, that it should not lessen this process of oxygenation, either by lessening the efficiency of respiration or by so altering the constituents of the blood as to lessen their capacity for receiving the oxygen from the pulmonary air vesicles and distributing it through all the tissues. This view has hitherto received far less attention than its practical importance demands. For there are in general use a considerable number of remedies that cause such changes in the blood as to directly lessen the internal distribution of oxygen and lessen nerve sensibility and muscular strength.

A few years since, when it was claimed that the chief danger in all febrile affections was the pyrexia or high temperature, and we were deluged with antipyretics largely consisting of coal-tar preparations, it was soon demonstrated that nearly all of them exerted their antipyretic influence by directly diminishing the reception and internal distribution of oxygen with corresponding cardiac weakness. Then followed the discoveries in bacteriology and the toxic influence of ptomains, toxalbumins, etc., and "heart failure," instead of pyrexia, was proclaimed as the chief source of danger in all the acute febrile and inflammatory affections. So true is that almost every work on the practice of medicine, issued during the past ten years, states in general terms that "progressive cardiac weakness" constitutes the chief danger to life in diphtheria, pneumonia, and nearly all the continued and eruptive fevers. And in equally general terms it is stated that to counteract such cardiac weakness "stimulants should be given early" and freely; often without indicating what stimulants are best or in what doses they should be given. But whenever any particular stimulants are mentioned, pretty uniformly, alcohol, strychnin, digitalis, ether and musk constitute the list. The real cause or causes of the dreaded heart weakness are not well ascertained or definitely stated, and consequently we have no rational or physiologic guide for the choice of remedies.

Two decades since, it was very generally attributed to the pyrexia, but now it is very generally said to depend on the action of the poison producing the disease or, still more, on the "toxic action of the poisons produced in the course of the disease."

And yet, what the poisons thus evolved during the progress of acute febrile affections capable of progressively weakening the heart, are, we are not informed except as they are called leucomains, ptomains and toxalbumins. Neither is it claimed that any of the medicines mentioned as cardiac tonics or stimulants are capable of either preventing the formation, or of neutralizing the action, of these poisons. For one of the most recent and authoritative writers truthfully declares that: "We are still without an agent which can counteract the gradual influences of the poisons which develop in the course of acute febrile diseases."

Perhaps if we keep in view the fact that the living body, in health, is constantly evolving poisons or toxic agents which, if retained in the blood and tissues, as certainly produce general functional disturbances and cardiac weakness as do any of the specific causes of general febrile diseases; and that they are prevented from so doing by the processes of oxidation and elimination, it may point us more directly to the real causes of self-poisoning during the progress of acute diseases, and also to the most efficient remedies. If it is true that a large part, if not all, of the toxic

agents or poisons being constantly formed in the healthy body are destroyed by processes of oxidation and leucocytic or cell activity, is it not more than probable that the poisons developed during the progress of febrile diseases accumulate and produce their depressing effects from diminished oxidation and cell activity; such diminished oxidation and cell activity being caused by the action of the primary cause or causes of the febrile disease? Among the most constant symptoms or conditions of acute diseases are, diminished efficiency of the respiratory process through which oxygen is supplied for absorption by the blood, and diminished elimination of the products of oxidation and cell activity. On the other hand, all those agencies that promote the oxygenation and decarbonization of the blood and promote cell activity, correspondingly improve the action of the heart and the efficiency of all the excretory functions. And all those who are at the present time treating febrile affections hydrotherapeutically claim, as the most marked effects of the frequent application of water, whether by spraying, packing or full baths, are increased tone of the cardiac and vascular circulation, with increased cell activity and elimination of the products of internal oxidation. But to gain these advantages there must be also free respiration of fresh air, to furnish the oxygen necessary for sustaining both nerve sensibility and muscular tone, as well as the processes of oxidation. Hence the declaration of M. Robin as the result of his numerous experiments and analyses, that "acts of oxidation are defensive processes of the organism in its struggle with bacteria, and therefore that the physician should favor, in every possible way, the absorption of oxygen in every infection, especially when there are typhoid complications," is one of the most important and far-reaching physiologic and therapeutic announcements on the pages of our current medical literature. It points us to the true pathologic effects of the pathogenic bacteria or their toxic products, in lessening the oxidation processes and cell activity in the blood, and the progressive cardiac weakness on the one hand; and on the other, to the use of such remedies as will either neutralize the toxic products or promote their oxidation and elimination. And to accomplish the latter we must have efficient respiration to supply the oxygen and capacity of the blood to receive and distribute it through the tissues and organs of the body. Consequently, the most efficient remedies to prevent or arrest the dreaded heart failure in all general febrile diseases, are such as directly increase the sensibility and action of the respiratory and vasomotor nerves and promote natural cell or leucocytic and secretory activity. It is very generally agreed that strychnin, digitalis, strophanthus, cactus and convallaria promote the efficiency of both respiration and circulation by their direct action on the respiratory and vasomotor nerve structures, and, at least indirectly, promote cell activity and secretion, while fresh pure air, judicious hydrotherapy and simple nourishment, add still more to the efficiency of the internal processes of oxidation and external excretion. On the other hand, not only nearly all the internal antipyretics, but all the well-known anesthetics, as chloroform, ether and alcohol, directly diminish the sensibility and action of the nerve structures generally and of the respiratory and vasomotor centers especially; and at the same time they equally diminish the leucocytic and cell activity and the processes of oxidation and elimination of toxic products. That the presence in the blood of

either chloroform, ether or alcohol, or of all combined, directly lessens the efficiency of respiration in proportion to the quantity present, impairs vasomotor activity and retards all the metabolic processes. has been so fully proved both by experiments and clinical observation as to need no further proof. On what possible basis, then, can we continue to class alcohol and ether as cardiac tonics or stimulants, in direct connection with strychnin and digitalis, to be given to the same patients on the same days and sometimes at the same hours, when the first two are so directly antagonistic in their physiologic action to the two latter? But my purpose in trespassing upon your time with this brief paper is simply to invite more attention to the fact that a true cardiac tonic must be an agent or remedy that not only increases the tone and efficiency of the heart, but also sustains, at the same time, cell activity, internal oxidations and respiratory and vasomotor nerve sensibility.

DISCUSSION.

Dr. BOARDMAN REED of Philadelphia—I have been much pleased by the paper of Dr. Davis, and especially by the emphatic manner in which he condemns the prevalent abuse of stimulants. Indeed, I have been for years watching with admiration his sturdy battle against this great evil. It seems to me most fortunate that a veteran of his long experience and distinguished ability should come forward as the uncompromising foe of such a crying abuse. Therefore, I regret the more at being obliged to differ from some of the views advanced by Dr. Davis in the paper just read. It seems to me that in discussing the place of alcohol in therapeutics a broad and clear distinction should be made between stimulants and tonics. Alcohol has no claim whatever to be considered a tonic. Indeed, its prolonged use always tends to develop cardiac weakness, as every clinician knows. But as a quick diffusible stimulant in emergencies, it is often a valuable help which we ought not to be deprived of.

Another point not touched on by the writer of the paper is that even drugs which are undeniably cardiac tonics, such as digitalis and strophanthus, may not be depended on to produce their tonic effects when they have been long administered. Experience shows that it is best to alternate these, giving one for a week or two and then changing to another of the group.

Dr. JOHN A. CUTTER of New York—I desire to thank Dr. Davis for his valuable paper. It is not at every meeting that one can learn from so old and careful a student as the reader. My experience with heart tonics is somewhat varied. I can thoroughly agree with Dr. Davis as to the value of proper breathing and fresh air. I have seen a case within an hour of death revive simply by the opening wide of the window and the air pouring in. Again, the use of oxygen or oxygen compounds as prepared by reliable manufacturers is of value in cases of heart weakness. When one considers that in many cases of sickness the blood has becomeropy and sticky from an increase of the fibrin filaments, and that the heart's labor is thereby increased by having to pump this self-same blood through the capillaries, which are only one three-thousandth part of an inch in diameter, having a leeway of one forty-eight thousandth of an inch for red blood corpuscles, the value of plenty of drinks of distilled water or water that has but five to ten grains of salt to the gallon can be easily imagined. I make the statement from experience and also as *contra* to some of the teaching in heart therapeutics which obtains at the present, that we should diminish the amount of fluids to diminish the work of the heart. If by giving plenty of fluids we dissolve the fibrin filaments and relieve the stickiness, the heart's labor is greatly diminished. Indeed, in consumption and rheumatism and thrombosis, I have seen the left side to be larger than the right, the heart having increased in size because of the extra work put upon it by this abnormal sticky, ropy blood stream and, after treatment, sometimes within two months' time, the heart is decreased in size and the left chest wall has come down to its normal condition. I consider this fact in medicine, which is known to others, to be one of the most astounding things to be met with because of its inherent value to the human race. Here again, then, drinks of hot water become heart tonics because they relieve the work of the heart. My teacher in medicine, Dr. Samuel B. Ward of Albany, was very positive in advising us students to relieve the liver in cases of heart complaint. It is only a few weeks ago that I found one of my patients in my office, a man who had

been a heavy drinker for years, very obese, and who suffered from stone in the kidney and who had been greatly relieved of his obesity and stone formation by careful treatment; the same was complaining of dizziness and on examination of the pulse I found his heart beating along weakly, at times quick and then slow. He admitted that he had been to an Elks' dinner the night before and had drank considerable liquor; he also had been overworking and lifting. Now, you know that in these "weak days" one does not often get hold of a strong robust patient to drug heavily; they all need lifting up. This man, outside of his weakness of that day, was powerful in chest and arms and could stand a rough and tumble fight such as he used to experience in the days when he was a Tweed politician. I said to myself, He is "my meat," and gave him one-twentieth grain of strychnia to steady his nervous system and heart, and three-fourths of a grain of podophyllin and three-fourths of a grain of aloin. I expected that he would report at the office the next morning in a criticising state of mind. Instead of that he came in about noon time, just twenty-four hours after I prescribed for him, as happy and feeling as fine as if he was a boy. The aloin and podophyllin acted on him twelve hours after exhibition and gave him a very liberal unloading of the liver; here again was a heart tonic by detergents. As to digitalis, I could not have sassed my wife in the last months of her life without this powerful medicine. She died of heart failure, having a normal but small heart and small cavities in both lungs which had been healed for seven years. For a year or more before her death, she used digitalis in one form or another. I got it all from Frazer's preparations in tablet form and gave digitalin, one-sixtieth of a grain, digitalis powd. one-fourth grain, and digitalis fluid extract one-half minim. I found that the last named was the most powerful of any of the preparations. She had lost her appetite some three years before her death and it was hard work to get nourishment into her. The cough would come on when she was tired, and in the last six or eight months of her life she suffered at times acutely from pain about the heart and down the left arm; I suppose a true form of angina pectoris, although I do not remember of her suffering from the terrible gasping pain, if I may so term it, which sometimes comes in true angina. Nevertheless, the pain in her left arm was severe and she said to me once after using the fluid extract one-half minim tablets, "That must be very powerful medicine to help me." It must be remembered in her case that she had careful nursing, drinks of the best of water and the best of food, as far as she could eat it; hence, she bore the digitalis a great deal better than if she had had no systemic treatment. I give this evidence of the value of digitalis because it was a great friend to her as well as to me.

Dr. A. E. MILLER of Boston—As a rule, heart stimulants are less satisfactory in their results than heart tonics. In many cases where stimulants are administered the heart is already working too fast, and the stimulant increases the difficulty; while heart tonics, as digitalis and nuxvomica, in small doses give more power, increase the force and diminish the frequency. This is especially the case in pneumonia and typhoid fever. When stimulants are freely used in these cases the mortality is increased. For several years I have been paying particular attention to the results of alcoholic stimulants in typhoid fever and have noticed that physicians who use alcohol freely lose many of their patients, while those treated without alcohol all recover. I have not known of a single death from typhoid fever for the past twenty years when the patient was treated without alcoholic stimulants.

Dr. HORACE P. MAKECHNIE of Somerville, Mass.—Sometimes when the heart is distended by pain, shock or distress of any kind, either mental or physical, sedatives such as small doses of morphin may act like a cardiac tonic by antagonizing the depressing forces. Has the reader noticed any such effect?

Silver Nitrate and Ergotin in the Treatment of Pulmonary Tuberculosis.—Before the Section in Medicine of the Twelfth International Medical Congress, Dr. Crocq of Brussels (*Progrès Médical*, September 4), maintained that tuberculous disease tended to end in recovery rather than in death, and that a fatal termination was due to an inflammation which led to a propagation of the tubercles. If this inflammation could be prevented or cured, there would be more cases of recovery. According to the author, we have no remedy against the bacillus; creosote does not kill it, and there are some inconveniences about its employment, especially as regards the management of the stomach. He has employed with much success, even in cases that were grave or complicated with diabetes, ergotin and silver nitrate. The latter, he says, acts very beneficially on the stomach.—*New York Medical Journal*.

TRANS-PERITONEAL LIGATION OF THE ILIAC ARTERIES.

WITH REPORT OF SEVEN NEW CASES AND STATISTICS OF TWENTY-NINE OPERATIONS.

BY THOMAS S. K. MORTON, M.D.

PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC, ETC.
PHILADELPHIA, PA.

A successful and eminently satisfactory operation for iliofemoral aneurysm having impressed the writer with the ease, accuracy and general superiority of the intra-abdominal or "transperitoneal" method for ligation of the iliac arteries, he has collected the published cases, twenty-two in number, to which, through the generosity of friends, he is able to add six hitherto unpublished cases, making with his own case a total of twenty-nine shown in the table.¹

Of the twenty-nine cases, twenty-two recovered and seven died. There were twenty-five different operators. Seventeen operations were performed by fifteen American surgeons. All of the priorities as to first operations and first successes rest with the Americans. To this country must also be credited the classic paper of Dennis (*Medical News*, Nov. 11, 1886), which at once placed the procedure upon an enduring basis.

Among the seven deaths, none were attributable to abdominal complications. The only instance of such complication was a partial obstruction of bowels in one case which necessitated reopening of the abdomen on the sixth day, but recovery nevertheless took place. The low mortality is remarkable when it is remembered that many of the cases were partially eviscerated prior to the introduction of the Trendelenburg position which has so much facilitated the operation. It is further remarkable, in view of the many operators and the fact that nine operations were done before 1890. Prior to that date five recovered and four died. Since 1890 seventeen have recovered and but three have died.

Common iliac artery.—Five cases. Of these four recovered and one died. The death was from gangrene. The first operation was by F. Lange, in 1883, and resulted fatally. The second operation and first success was by the same surgeon and in the same year. The three remaining successful operations were by Lucas, in 1889; Thornton, in 1894, and Stevenson, in 1896.

Internal iliac artery.—Nine cases. Of these seven recovered and two died. One death was from nephritis on the sixth day, the other from recurring hemorrhage from a septic wound of the buttock on the thirteenth day. The first operation was by Le Roy McLean, in 1872. It was not successful. The first success was that of Dennis, in 1886. Two were double simultaneous ligations; one by Dennis in 1886 for double gluteal aneurysm, with death from nephritis on the sixth day; the other by Kelly, in 1893, for uncontrollable hemorrhage during hysterectomy for carcinomatous uterus, with a successful result.

External iliac artery.—Fifteen cases. Of these eleven recovered and four died. Two of the deaths were due to subsequent gangrene of the extremity, one to shock and hemorrhage preceding the operation, and the fourth to shock from loss of a "gallon of clots" from an aneurysm which was opened after ligation of the supplying vessel. The first operation was performed by Richardson in 1886, with fatal result. The second operation and first cure was by Stimson, in

1889. Makins ligated the external iliac on one side for aneurysm, in 1892, and upon the same patient a year later performed the same operation on the opposite artery, for a similar condition. The patient recovered also from the second operation.

A considerable correspondence with surgeons of this country and Great Britain has convinced the writer that the general opinion among operators is decidedly in favor of the transperitoneal route for all ligations above the lower portion of the external iliac. When the latter portion can be tied by the old extraperitoneal method it continues to be preferred. But if the disease involves any tissue above Poupart's ligament and, in any case, for higher ligations, almost all are emphatic in condemning the frightful old-fashioned incisions from the groin and loin; some going so far as to exclude the teaching of them from their lectures to students. The Trendelenburg position is a great aid in these operations and does away with the risks of evisceration and strong pressure by retractors that was considered necessary in some of the earlier operations. But neither this position nor injurious pressure are necessary in the average case, although the elevated pelvis undoubtedly renders the procedure more easy. Under scarcely any possible circumstances could evisceration be justified today.

Incision for low ligations should be lateral. The semilunar line has been the favorite site, up to the present time, for the external iliac, but in this case, perhaps, it will be found that the ligation can as well be performed through an adaptation of McBurney's muscle-splitting incision for appendicitis and thus do away with all danger of subsequent hernia. In case of ligation of the internal or common iliacs the median incision has in all cases been found best. Suture of the peritoneum overlying the sheath of the vessels has not been found essential, although probably desirable if the condition of the patient should permit.

CASES HERE FIRST PUBLISHED.

Case 1.—Dr. LeRoy McLean of Troy, N. Y. (Personal communication through Dr. C. B. Herrick.) "In 1872, a female, aged 50 years, received a stab wound in the right buttock, which was followed by profuse hemorrhage. Her attending physician closed the wound with a number of sutures, thereby stopping the bleeding. The same remained closed, but about two weeks thereafter a swelling appeared in the gluteal region, for the relief of which she presented herself at the Troy Hospital, coming into the service of Dr. McLean. He found an aneurysm which, from its location and the situation of the stab wound, he decided to be of the internal iliac artery. He thereupon opened the abdominal cavity in the median line, just above the pubes, making a short incision, pushed the intestines aside and coming upon the internal iliac artery, slit through the posterior layers of the peritoneum, and passed a ligature about the vessel by means of an aneurysm needle. The case went well; the abdominal wound healed promptly; no peritonitis or rise of temperature was noted. After about thirteen days the old stab wound suddenly broke out afresh and hemorrhage took place to a considerable amount. Despite treatment directed to the prevention of the same by pressure and ordinary means used over the site of the tumor, the hemorrhage continued from time to time until the patient succumbed through exhaustion."

"Postmortem revealed the artery cut off close to its emergence from the pelvis, and the presence of a good-sized aneurysmal sac. Silk was the material used for the ligation, and chloroform the anesthetic."

Case 2.—Dr. Thomas G. Richardson of New Orleans. (Extracts from letter of Dr. R. Matas of New Orleans.) The patient, an adult male, was brought to the Charity Hospital in the winter of 1886 or 1887, wounded in the thigh high up in Scarpa's triangle. He was much exhausted from shock and hemorrhage. To control bleeding Dr. Richardson made an incision directly over the course of the external iliac, cutting through abdominal wall and peritoneum and secured the external iliac between its origin and Poupart's ligament. The man died some time

¹ One case, No. 29 of the table, has been added since the paper was read.

subsequently, of shock and the effects of previous loss of blood, presumably.

Case 3.—Dr. George R. Fowler of Brooklyn. (Extracts from records of Methodist Episcopal Hospital of Brooklyn.) M. C., aged 16, was admitted to the hospital July 3, 1893, with the following history: About four years prior to admission he suffered from double suppurative inguinal adenitis. The left side was incised; the right opened spontaneously. Shortly after this he noticed that the right lower extremity was larger than the left. This enlargement increased steadily for six months, since which time the relative proportions of the two limbs have remained stationary. He suffers no pain: the inconvenience present is mainly due to the increased weight of the limb. Examination shows the right limb to be the seat of a uniform swelling, as compared with the left. The skin presents the coarse or exaggerated appearance of elephantiasis. The swelling does not pit upon pressure. Measurements: Left, or normal leg; above ankle, 8 inches; at knee, 12; thigh on level with perineum, 16.5 inches. Right, or diseased limb; above ankle, 10.5 inches; at knee, 16; thigh at level of perineum, 21.5 inches. Operation, July 11, 1893. Patient was etherized and placed in Trendelenburg's position. The cavity of the abdomen was opened by a three-inch vertical incision in the right linea semilunaris. The intestines were held back, the external iliac artery identified, the posterior reflection of the peritoneum incised, the vessel isolated and surrounded by a catgut ligature. The vein was found lying to the outer side of the artery. The patient suffered very slightly from shock. The limb was bandaged in cotton and kept elevated. He suffered no inconvenience from the operation and at no time was there sufficient embarrassment to the circulation to cause anxiety. He was discharged cured on August 28, at which time the measurements were as follows: Right calf, 12.25 inches; knee 13.25; thigh, 15 inches. Left calf, 11.25 inches; knee, 12.5; thigh, 15 inches."

Case 4.—Dr. W. Joseph Hearn of Philadelphia. A. B., aged 43 years, was admitted to the Jefferson Hospital in June 1890 suffering from an aneurysm of the popliteal artery. The patient was of slight build and light complexion, a painter by occupation. His general health had been good and he had never contracted syphilis. None of his relatives had ever suffered from tuberculosis. The tumor was the size of a small orange, impeded motion and caused loss of sensation. The femoral artery was ligated with silk, in Scarpa's triangle. From this operation the patient made a good recovery. The tumor gradually subsided and he left the hospital in four weeks, collateral circulation being well established. In August 1893 he returned to the hospital with a pulsating tumor in the left pelvis. He had suffered with some pain and discomfort for three months prior to his again coming under observation. Examination proved the tumor to involve the left external iliac artery, apparently through its entire extent. The size of the mass and the uncertainty as to the length of the artery involved led to a choice of the transperitoneal method. An incision four inches long was made in the left linea semilunaris. The patient being in the Trendelenburg position, by means of broad retractors protected with gauze, it was possible to keep the intestines out of the way and to secure an excellent exposure not only of the tumor but of the aorta, common and internal iliac arteries. Two inches of the external iliac was found uninvolved and, therefore, a ligature was placed upon it just below the bifurcation of the common iliac artery. With two pairs of forceps the postperitoneal membrane was slightly torn over the artery and an aneurysm needle armed with stout silk was passed from within outward. Previous to passing the needle, the grooved director was employed to free the vessel from its attachments. The peritoneum overlying the vessel was approximated by a single catgut suture. The patient made a good recovery. The temperature never passed 100 degrees. He had some distress from distention of bowels and retention of urine, however. Three years later he was in excellent health and able to work at his trade. The left limb was somewhat atrophied and a little weak.

Case 5.—Mr. Frank T. Paul of Liverpool, England. J. E., a man aged 38 years, a gas-fitter by occupation, was admitted to the Liverpool Royal Infirmary June 13, 1895, complaining of a "lump having formed in his right groin." His family history was negative, while his six children were all healthy. He contracted syphilis when 19 years of age, but the only signs of that disorder remaining when he came under observation were evidences of old iritis. Six months before admission he had a "running abscess on the left side of his seat which healed up of itself." One month before entering the hospital he helped to lift a piano and thought that he had strained himself. Ten days afterward he noted a slight pain in his right groin and a few days later observed a swelling. The tumor had not increased in size since he first noticed it and caused very little

local pain. On inspection, an ill-defined pulsating swelling could be seen in the patient's right groin, lying in Scarpa's triangle and extending downward three and one-half inches from Poupart's ligament. Its greatest breadth was about two inches. On palpation the tumor was felt to be hard, elastic and pulsating. Its shape was fusiform. Expansile pulsation was very marked and a systolic bruit could be detected with a stethoscope. The heart sounds were normal; the kidneys and other organs were likewise in a healthy condition. On June 17, an incision four inches in length was made from above downward along the outer border of the right rectus muscle, taking care that it was placed well outside the deep epigastric artery. The tissues of the abdominal wall having been divided, the intestines were displaced from the iliac fossa and retained clear of the seat of the operation by a sponge held by an assistant. The position of the external iliac artery became at once apparent and it was very easily ligatured through a small opening in the posterior peritoneum. It was tied with ordinary carbolized catgut and the small opening in the peritoneum over it was closed with two fine sutures of the same material. The artery where ligated was healthy, and there was no bleeding whatever into the peritoneal cavity. The external wound was closed with fishing-gut sutures passed, as usual, through all layers, particular care being taken not to perforate or include the deep epigastric vessels. The limb was wrapped in cotton wool, lightly bandaged with a soft bandage and placed upon a pillow. On June 18 the limb was warm and of good color. On July 2 the abdominal wound was healed and there had been no complications. The aneurysm was hard and no pulsation could be detected in it or in any of the vessels of the leg or foot. On July 12 pulsation had appeared in the dorsalis pedis artery. He was permitted to be up and about. On July 27 he was discharged well, except that there was a slowly diminishing hard tumor in the place of the aneurysm. In January, 1897, the patient was again seen by Mr. Paul, who found that he had increased twenty eight pounds in weight since the operation, and that he was able to work at his trade without any disability whatever. The right leg was then a little weaker and smaller than its fellow and the pulsation in its arteries was not equal to the left extremity. Still this gave him no annoyance, and he was able to put in full time at arduous work.

Case 6.—Thomas S. K. Morton of Philadelphia—J. R., colored, aged 48 years, by occupation a waiter, was admitted to the Philadelphia Polyclinic Hospital, April 4, 1895, suffering with a large swelling in the left groin. His family history was negative. When 17 years of age the patient had syphilis and was under treatment a full year. From that time he had remained in excellent health until one year prior to entering the hospital. Then, a short time after straining himself in lifting a heavy piece of iron, he noticed pain and tumefaction in the left groin. The tumor had steadily enlarged. It was the size of an orange and situated mostly below Poupart's ligament in the line of the common femoral artery. Above the latter ligament there was also a considerable expansion of at least one inch of the external iliac artery. The growth presented all of the signs of aneurysm. The leg on the affected side was quite edematous. The man was put to bed with the left leg slightly elevated and instructed to stop the circulation through the aneurysm occasionally, by pressure upon the external iliac through the abdominal wall. In doing this he was very successful. On April 8, under ether anesthesia, a four-inch-long median abdominal incision was made below the umbilicus. A strong retractor was introduced upon the right side of the wound and the intestines held away from the vessels on the left side. The external iliac artery and vein were then readily brought into view and identified. The peritoneum overlying the sheath was divided with knife and forceps to the extent of one inch. Then an aneurysm needle was carefully insinuated between the artery and vein, carrying through a single loop of silk. By means of the loop, three strands of medium size silk were carried around the artery without any especial trouble. Everything and every manipulation was in plain view throughout. The three strands of silk were next tied down one by one upon the vessel, after the manner of tying what Ballance and Edmunds have termed the "stay" knot, that is, each ligature is double twisted and tied firmly down for the first tie; the second tie is made from the three or more ends on each side tied down as if one strand. This gives a certain occlusion of the vessel by bringing a considerable extent of its walls into firm contact.² The site of the ligature was about three quarters of an inch below the bifurcation of the common iliac. The peritoneum over the ligature and sheath was not sutured as it naturally fell together along its divided edges. The

Recover'd. Well 4 years later.	Intestinal obstruction, incomplete. Wound opened on 6th day, kink in small intestine.	Recover'd. Complete recovery.

entire extremity was done up in thick layers of cotton batting after the abdominal incision had been closed by storied sutures. External heat was also applied to the limb for forty-eight hours. It was kept slightly elevated. The leg remained slightly cold and numb for twelve hours, but then warmed up and full sensation returned. Recovery was without rise of temperature or any complication. Good collateral circulation was present in the tibials within two weeks, at which time he was permitted to sit up and gradually get about. The tumor in the groin gradually shrank and was no larger than a hen's egg in six weeks. At the present time (June, 1897) the man continues in the best of health. There is little more than a heavy fibrous cord in the groin, excellent collateral circulation, and absolutely no interference with the motions and utility of the affected side. The abdominal incision shows no sign of weakness.

Case 7.—Dr. Frederick Lange of New York.—Man, aged 60 years; large aneurysm above Poupert's ligament involving external iliac artery on the left side; ligation of left common iliac artery by transperitoneal route; subsequent gangrene of leg; high amputation of thigh; death.

MELANOSARCOMA OF THE CONJUNCTIVA, WITH THE REPORT OF A CASE.

Presented in the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY ALBERT RUFUS BAKER, M.D.

PROFESSOR OF DISEASES OF THE EYE, EAR AND THROAT, CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS; OCULIST AND AURIST TO THE CLEVELAND GENERAL, ST. ALEXIS AND CITY HOSPITALS. CLEVELAND, OHIO.

Mr. G. of Cambridge Springs, Pa., aged 69 years, was first seen in March, 1888, with a dark purplish lobulated tumor of the left eyeball, about three quarters of an inch in length, one-half inch in breadth and about one-half inch in thickness, springing from the ocular conjunctiva on the nasal side. The tumor was first noticed about one year previously as a small dark spot. There was no history of traumatism.

There was diplopia when looking to the right, owing to the tumor preventing the eye rotating in that direction. There was slight haziness of the lower part of the cornea, probably due to the imperfect closure of the lids, but otherwise vision was good. A fairly satisfactory ophthalmoscopic examination was possible, revealing a healthy fundus. The tumor was slightly movable, but I was uncertain whether or no it was adherent to sclerotic or deep orbital structures. There was no pain and the patient refused to have the tumor removed.

During the next three months the tumor grew rapidly and began to fungate and bleed frequently. During the early part of June there were two or three hemorrhages, which were controlled with great difficulty by compress bandages. It was only after becoming thoroughly alarmed by these hemorrhages that the patient consented to have the tumor removed, which at this time presented an ugly, black mass, filling the palpebral opening and completely covering the eyeball.

Ether was administered and every precaution taken to control excessive hemorrhage, and preparations were made for extensive dissections of the orbit together with the sacrifice of the eyeball. Indeed, a formidable operation was anticipated, but much to our surprise, the tumor was found to be pedunculated, very superficially attached to the conjunctiva, and removed easily with the forceps and scissors with very slight hemorrhage, leaving a perfectly clean wound of the conjunctiva which was partially closed with sutures. The wound healed kindly but was followed by a slight entropion, owing to the cicatricial contraction. This

was relieved by an operation one year later. The patient was seen three years after the operation, vision perfect in both eyes, no recurrence of tumor and general health excellent.

The tumor removed was the shape and almost the size of a hen's egg, hard and black, round and smooth, excepting on the larger fungating end. Dr. Chr. Sihler, professor of histology in the medical department of the Western Reserve University, examined the tumor microscopically and pronounced it a small celled melanosisarcoma with much pigment.

Mr. Gerrish died September, 1893, five years and three months after the tumor was removed from his eye. An autopsy was held by Dr. W. N. Young, together with the assistance of several physicians of Cambridge Springs, Pa. Death was due to a large cancerous growth of the liver, probably melanosisarcoma.

It seems as though there should be no difficulty in distinguishing these conjunctival tumors from intra-ocular ones which, having penetrated the sclerotic, present externally. Unlike some of our mistakes, this may prove disastrous to our patient. Few would object to the removal of the tumor if assured that the eyeball need not be sacrificed. I fell into this error and only recognized my mistake during the operation. In the light of my present experience the error seems almost inexcusable.

Several cases of non-pigmented sarcoma of the conjunctiva have been reported, but they are probably much less frequent than the pigmented tumors. The sclerocorneal limbus seems to be a not very infrequent location for epithelial cancers. They are usually non-pigmented, sessile, flat tumors of slow growth with an early tendency to ulcerate.

The melanotic sarcoma of the conjunctiva, like the epithelial cancer, is peculiar to old people, although a few have been reported in young persons. Carcinomatous growths of the conjunctiva have been recorded by a number of writers, and may or may not be pigmented. Indeed, the statement of "Noyes" that the occurrence of pigmentation is a feature entirely incidental and not essential to the growth of the tumor seems probable." Although melanotic tumors of the conjunctiva are comparatively rare, I am inclined to think they are more common than the literature of the subject would lead us to infer.

Walton² states that in three cases in which he removed the eyeball for a chronic fungus state of the conjunctiva, he found upon dissection the coats and other parts of the eye to be quite unaffected and in their natural state.

Travers³ gives a beautiful illustration of a case in which he performed abscission of the anterior portion of the eyeball.

Dr. Jacob⁴ reports a case of a black, spongy tumor, two inches in diameter, overlapping the eyelids in all directions so as to nearly close the whole opening of the orbit. It appeared to be attached to the eyeball with a cylindric stalk which was slightly enclosed by the eyelids. Being prepared to remove the contents of the orbit, if necessary, Dr. Jacob drew his knife across the stalk as a preliminary operation, and found that he had incised a healthy eyeball, the disease being confined to the conjunctiva. The divided eyeball healed kindly. The subsequent history of the case is not recorded.⁵ Cases have been reported in more recent literature in which the eyeball has been unnecessarily sacrificed.

These melanotic tumors of the conjunctiva seem to

present an exception to the general surgical principle in malignant growths, that the dissection should be made as distant from the tumor as possible. It is not impossible that these cases may occasionally result in spontaneous cure.

Some time since, Dr. A. P. Ohlmacher⁶ presented to the Cleveland Medical Society two specimens taken postmortem from a man who had had trouble with his eye four years before the liver trouble, from which he died, began. The duration of the liver trouble was about one year. The relation of the enlarged liver to the eye disease was suspected by the physician in charge of the patient, but it was thought to be echinococcus disease, and an operation was undertaken to remove the suspected hydatids. The interior of the eye was occupied by a small black tumor which showed, on microscopic examination, all the characteristics of melanotic sarcoma. A curious feature, says Dr. Ohlmacher, of this growth is its tendency to atrophy and shrink with the eyeball instead of increasing in size and breaking through the eye, as is usually the case. A line of pigment along one side of the optic nerve probably marks the route by which the tumor germs escaped from the eye to produce the metastatic infection. The liver with the metastatic, melanotic sarcoma weighs fifteen pounds.

Dr. Mathewson reported a case somewhat similar in the "Transactions of the Amer. Ophthal. Society" in 1874. Dr. Mathewson's case subsequently died, melanotic tumors appearing over the entire surface of the body, as well as in the internal organs.

Dr. Randall⁷ observed a case in Jaeger's clinic, a large pedunculated tumor, apparently tending toward spontaneous recovery.

In my case the pedicle was so small, in comparison with the size of the tumor, that it might have been possible for the entire growth to have dropped off from its own weight, and the pressure of the lids upon the pedicle behind it. At least a slight twist so as to cut off the circulation might have accomplished this result, yet these tumors may grow to an immense size.

Mr. Abernathy⁸ refers to a curious case of a sarcomatous tumor of the conjunctiva which did not involve the cornea, which was clear and transparent. The tumor pushed out between the eyelids and was seven inches long, three and one-half in circumference, and weighed when extricated two and one-half pounds. More information as to the subsequent history of these cases would be of great interest. This might be a good subject for collective investigation.

There seems to be great indefiniteness as to how frequently and how soon recurrence of melanosisarcoma of the conjunctiva may occur, and in what proportion metastasis may be expected after removal. De Wecker⁹ intimates that we should be extremely cautious about operating on these tumors. He says cases have remained absolutely stationary for twelve or even twenty years, while if operated on they sometimes recur with fearful rapidity, or what is perhaps worse, undergo metastasis. If convinced that general infection is not immediately imminent, he advises enucleation of the eye at once; but no such operation should be ventured on if previous attempts have already produced a return of the disease *in situ*, or if the blood is contaminated. In that case metastasis will happen almost to a certainty.

As an illustration of the difference of opinion held by members of the profession as to the question of metastasis, Strause¹⁰ offers as one of his conclusions:

"Metastasis practically never occurs." The latter conclusion does not seem to be warranted by the history of these cases as recorded by many observers.

Fuchs¹¹ reports a case of typical melanosisarcoma that was first excised in 1879. In May, 1886, it returned on the opposite side of the cornea of the same eye. It was again removed and returned. In September of the same year the eye was enucleated, and six months later it returned in the bottom of the orbit. Complete exenteration of the orbit was then performed. The patient died from extension of growth to internal organs in February, 1890.

Cases dying from metastasis have also been reported by Ole Bull¹² and others.

THE SURGICAL TREATMENT OF TRACHOMA.

Presented in the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN E. WEEKS, M.D.

NEW YORK, N. Y.

The scope of the present paper will not admit of a review of all of the operative procedures that have been and are now employed in the treatment of trachoma, even if it were desirable. I shall, therefore, mention but few and, as I believe that a discussion of methods employed by the individual speakers here is more suitable and will be more profitable to those present, I shall conclude by describing the method that I find most generally useful.

Viger (*Annal. d'Oculistique*, 1892, p. 175) scarifies horizontally and transversely and brushes in a solution of sublimate, 1 to 500. He then applies compresses dipped in a hot solution of sublimate, 1 to 5,000. The after-treatment is by daily applications of sublimate solution, 1 to 500.

Armaignac (*Annal. d'Oculistique*, Vol. cx, p. 121) employs a method which he terms "Tattouage médicamenteux." With a bunch of tattooing-needles the whole affected portion of the conjunctiva is repeatedly pierced; at the same time the surface of the conjunctiva is bathed in a solution of sublimate, 1 to 500. Afterward the brush is employed with the same solution. He states that after some weeks the granulation tissue entirely disappears leaving a smooth surface.

Ottawa (*Annal. d'Oculistique*, Vol. cx, p. 45) employs massage.

Blubaugh (JOUR. A. M. ASSN., Oct. 14, 1893) uses a series of scrapers for scraping away the granulations and then gives the patient a "lump of alum," directing him to rub the conjunctival surface as the case demands. The patient is permitted to go home.

Excision of the retrotarsal fold is still advocated by some surgeons (Venneman, *Arch. d'Oph.*, Paris, 1894, p. 413).

Experience in the surgical treatment of trachoma, extending over a number of years, causes the writer to proceed as follows: All operations for marked trachoma are performed under ether or chloroform

anesthesia. Cocain anesthesia is not sufficient and, if attempted, results in causing the patient pain and unduly hastens the work of the surgeon. After cleaning the eyes, the margins of the lids are seized in turn by means of the clamp forceps and the lid is rolled over the blades of the forceps. This serves to expose, almost if not quite, the whole surface of the conjunctiva.

With a scarificator bearing three Demarre's blades and supplied with a guard to limit the depth of the incisions, superficial incisions parallel to the margins of the lids are made into the trachomatous tissue. The conjunctival fold is then seized with the Noyes or Knapp trachoma forceps, preferably the former, and held between the blades of the forceps. If on raising the fold of conjunctiva it is found that some of the trachomatous tissue has escaped scarification, the remaining portion is scarified. The incisions should run parallel to each other; they serve to uncap the trachoma follicles and to permit of the easy escape of the masses of lymphoid cells which form the bulk of the trachomatous tissue. By a gentle stripping motion, avoiding undue pressure and tearing of the conjunctiva, the contents of all of the follicles in fornix, tarsal and caruncle conjunctiva are evacuated. A moderately soft tooth brush is then employed to introduce a solution of sublimate 1 to 500 into the conjunctival tissue and incidentally to cleanse the membrane, but little force being employed. The conjunctival sacs are then irrigated with a solution of sublimate, 1 to 5,000, to clear them of all particles of blood clot, and finally an ointment of sublimate 1 to 5,000, in vaselin is applied to the conjunctival surface by means of a glass rod. A piece of moistened gauze is then laid on the lids and the eyes bandaged for twenty-four hours. The bandage serves to control any edema that might arise if slight pressure were not applied. The patient does not experience pain after the operation and surprisingly little reaction follows. The bandage is removed after twenty-four hours and the after-treatment is commenced. On inspection, when the bandage is removed, a layer of plastic lymph (pseudomembrane) will be observed covering the affected conjunctiva, and a tendency to adhesion between apposed folds of the conjunctiva will be noticed. A few drops of cocain should be instilled into the conjunctival sacs and after a few minutes the sacs should be cleansed by irrigation with a solution of sublimate, 1 to 5,000. After drying, the adhesions between the folds of conjunctiva should be gently broken up by means of a small glass rod, with a smooth round or slightly pointed end, or a metal probe of fair size carrying and being lubricated by a liberal quantity of the sublimate ointment above referred to. The layer of plastic lymph should not be disturbed except where it is concerned in forming adhesions between folds of the conjunctiva. The pseudomembrane forms a smooth surface, under which the repair of the conjunctiva progresses most favorably, and is cast off in a few days disclosing a very satisfactory condition of the conjunctiva.

If any feeling of discomfort is experienced by the patient, cold applications may be made to the lids after the procedure just referred to, which may be continued for one or two hours. There is no necessity for reapplying the bandage. Patients usually open the eyes and suffer little or none. The introduction of the ointment renders the tendency to the adhesion of the conjunctival folds less; however, the adhesions

that do form *must be broken up*, in the manner described, every twenty-four hours until the epithelial layer is completely restored, when the formation of the adhesions will cease. This usually takes about six days. No other treatment is necessary during this time, except that the patient may be directed to bathe the eyes with a solution of boric acid two or three times a day to ensure cleanliness. He may be permitted to be about as usual after the first forty-eight hours. The patient is now given a solution of sublimate, 1 to 8,000, to drop into the eyes three times a day and the surgeon may apply the ointment as above or an astringent, as appears necessary, every second day. Treatment other than a wash to ensure cleanliness may be discontinued in two weeks from the date of the operation. Recovery with a smooth elastic conjunctiva usually occurs in three weeks. This method is thorough, entails but little suffering and ensures good results in all cases in the stage of hypertrophy, and in the second stage in cases where the contraction has not advanced too far. If there is marked shortening of the palpebral fissure, the writer does canthoplasty, limiting the extent to the requirements of the case.

In exceptional cases where few trachoma follicles are present but are persistent (as sometimes occurs in private practice), the above described procedure, to a much less degree, is carried out, cocain anesthesia being relied upon.

The advantages that this method possesses are: 1. The easy removal of the trachomatous tissue, facilitated by the shallow scarification. 2. The thorough antisepsis without deterring the healing process. 3. Recovery with a smooth surface and minimum contraction.

One point the writer wishes to emphasize is that the after-treatment must be carefully carried out after this as after other operative procedures for trachoma, otherwise unpleasant adhesions between folds of conjunctiva, with a decided lessening of the area of the conjunctiva will follow.

A COMPARISON OF THE VALUE OF LOCAL MEDICINAL MEASURES IN THE TREATMENT OF GRANULAR CONJUNCTIVITIS (TRACHOMA).

BEING A PORTION OF THE REPORT OF THE SPECIAL COMMITTEE APPOINTED TO DISCUSS THE SUBJECT OF GRANULAR CONJUNCTIVITIS (TRACHOMA) FOR THE SECTION ON OPHTHALMOLOGY OF THE AMERICAN MEDICAL ASSOCIATION.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY H. V. WÜRDEMAN, M.D.

Ophthalmic and Aural Surgeon to the Children's Hospital; to the Milwaukee County Hospital for the Chronic Insane; Director to the Wisconsin General Hospital, Etc.
MILWAUKEE, WIS.

Study of the extensive literature upon the subject of granular conjunctivitis shows that the vane of fashion in its treatment has veered somewhat from the radical surgery in vogue several years ago to which it had pointed after years of silver and blue-stone cauterizations. Appropriate general treatment and regimen together with local medicinal applications in connection with surgical procedures are again in favor.

To scientifically discuss the value of local medicinal measures it is first necessary to consider the nature of

the diseased process. Examination of the vast mass of literature upon the treatment of granular and trachomatous disease shows that the authors' main ideas are to empirically cut, squeeze, burn and cauterize away the follicles and trachoma bodies in order to remove the supposed mechanical effect caused by their presence. I will attempt to properly expose the principles of scientific local medicinal treatment as well as to show the comparative value and action of many of the remedies that are now used in the cure of this disease.

Those chronic inflammations of the conjunctiva which by secondary infection or by metamorphosis ultimate in the trachomatous state pass through the following distinct stages, in whole or in part:^{16 30}

Figure 1.

1. The stage of epithelial proliferation, which is a catarrhal condition in which the functions of the cells in reference to their multiplication and the production of mucus is increased (Fig. 2). Here detergents, antiseptics and other treatment directed toward relief of inflammation is indicated.

Figure 2.—Epithelial proliferation.

2. The stage of superficial destruction in which the superficial epithelial elements are partially destroyed, but which by the healing process may be entirely reproduced (Fig. 3). In this condition surgical removal of contents of follicles and hyperplastic tissue, together with stimulating measures directed toward resorption of the trachomatous masses and regeneration of the epithelial, as well as detergents and antiseptics are needed.

3. The stage of total destruction of the epithelium which embraces those grave inflammations which, though well held apart by macroscopic signs, have for a common characteristic the destruction of all the epithelial elements on the surface of the conjunctiva (Fig. 4). In this stage, relief of complications and sequelæ, stimulation of the local nutrition to aid in resorption of cicatricial tissue and regeneration of the epithelium through stimulation of that remaining in the conjunctival crypts are the most important indications.

Figure 3.

4. The result of chronic granular disease is xerosis, and is attended by total destruction of all the mucous elements, the conjunctiva being replaced by connective tissue. This is incurable, but symptoms may be partially subdued by emollients.

Figure 4.—Total destruction.

The alteration of the epithelium and infiltration of the tissues are the only constant anatomico-pathologic phenomena and our treatment should be directed toward the removal of the causes of its destruction and to effect its regeneration.^{19 20 30} In this article I will pay no further attention toward prophylaxis, general treatment and surgical procedures in this disease, except to state that local applications are in most instances only a portion of the treatment and all grave cases must be treated surgically as well.

The local treatment of granular conjunctivitis may be described under the following headings: 1. Detergents. 2. Antiseptics. 3. Subjection of acute inflam-

mations. 4. Stimulation of nutrition. 5. Mechanical or surgical removal of the products of the inflammation, contents of follicles, hyperplastic tissue, etc. 6. Relief of asthenopic symptoms. 7. Relief of complications. 8. Relief of sequelæ.

1 and 2. Be it believed that one or several forms of germs or spores together with other causes form this disease, it is considered necessary to use antiseptics which may hinder their growth with as little destruction of the tissues as may be consistent with resultant recovery of the function.³⁰ For the patient's use, weak solutions of boric acid (2 to 5 per cent.), bichlorid^{20 27 29} and cyanid¹³ of mercury (1 to 5,000 to 1 to 10,000) as detergent washes are recommended. Instillation of stronger solutions fortified or guarded by antipyrin (0.5 to 3 per cent.), weak eucain (0.5 to 1 per cent.), cocain (0.25 to 1 per cent.), or holocain (0.16 to 0.25), are gratefully borne by the patient. The washes and collyria act superficially and are little more than detergents, but are particularly useful in the first and second stages of the disease. Yellow oxid of mercury ointment (0.33 to 2 per cent.), and ointment of ichthylol^{8 21} (1 to 5 per cent.), are antiseptics as well as stimulant compounds. Far more effect is produced by local application of antiseptics directly to the diseased membrane by skilled hands, and many cases are no doubt cured by such means alone. Brushing by the nitrate or iodid of silver (0.5 to 5 per cent.), aqueous or glycerin²⁹ solutions of bichlorid of mercury (1 to 10,000 to 1 to 100) or lactic acid²⁵ (2 to 20 per cent.) cause considerable reaction and the first stains the conjunctiva if used for any length of time. Argentamin^{14 22} (5 to 20 per cent.), cyanid of mercury (1 to 10,000 to 1 to 100) and boro-glycerid⁶ (5 to 25 per cent.), are not open to this objection. The tannate of quinin³ in solution (5 to 20 per cent.), antipyrin¹⁶ (3 to 25 per cent.), or resorcin¹¹ (1 to 10 or 1 to 5 in boric acid solution or powder) dusted on the surface of the conjunctiva, are antiseptics. (Powders are later considered in this article.) The submucous injection of sublimate²⁶ has been recommended in trachomatous pannus.

3. Iced applications or cold bathing together with the silver compounds are useful in the first grade of the affection when there is acute inflammation and when the secretion is free. Irritation may be limited by the use of cocain, eucain or holocain in collyria, to which boric acid or baborate of sodium may be added.

4. Hot water bathing or hot applications are among the best stimulants to nutrition in the second and last stage of trachoma. Bathing is usually ordered as hot as may be comfortably borne, for five minutes at a time from twice to a dozen times a day. Hot compressing is best made for periods of one-half to one hour a number of times a day, the compresses being changed every minute or two. To these applications antiseptics may be added. I have had gratifying results from a jet of steam applied for three to five minutes once a day to the everted eyelids.

After the acute state has passed most cases require stimulating applications of silver, mercury, copper and zinc compounds. It is well not to destroy the epithelium by corrosive antiseptics or caustics in the hope of thereby invoking secondary reaction for the purpose of stimulating nutrition or with the idea of destroying the germs in the subconjunctival adenoid tissue.

Nutrition may be actively increased by local mas-

sage with yellow oxid of mercury ointment (0.5 to 2 per cent.) placed in the conjunctival cul-de-sac and massage practiced through the lids for three to five minutes at a time, or what is better, the retrotarsal folds may be strongly reverted and the ointment rubbed into the mucous membrane by some smooth instrument for several minutes. In cases inapplicable for treatment by scarification, expression, picking out or cauterization of individual granulations, stimulation may be effected by massage with impalpable boric powder, iodoform, calomel or aristol rubbed in by the fingertip, or by hard rolled pledgets of cotton dipped in olive oil, or by massage with the finger alone, or by an instrument with or without medicaments. Rubbing down of the granulations by pumice stone, instillation of crude petroleum,⁷ ichthyol,^{8,21} boric acid and resorcin,¹¹ glycerite of tannin,⁶ etc., act largely by stimulation. The application of alum, sulphate of copper, nitrate of silver, lapis divinus and muriate of ammonium in pencil form act in the same manner.

Jequirity in weak solutions¹² (0.5 to 2 per cent.) three to seven times a week is said to be a powerful irritating stimulant: where used in strong infusions for the purpose of causing an artificial conjunctivitis it is the over-stimulation of the healing process which causes absorption of the granulations and redundant tissue.

5. Mechanical and surgical procedures for removal of the granular contents of the follicles, etc., are most applicable in the second stage and must generally be supplemented by medicinal methods of treatment.

6. Aside from asthenopic symptoms caused by refractive and muscular errors, weak sight is likewise due to conjunctival irritation. This is to be remedied by protective glasses, by hot or cold bathing, collyria of boric acid (2 to 5 per cent.), borate of sodium (2 to 5 per cent.), sulpho-carbolate and sulfate of zinc (1 to 5 per cent.), etc., usually with the addition of antipyrin (0.5 to 3 per cent.), eucain (0.5 to 1 per cent.), cocain (0.25 to 1 per cent.), holocain (0.16 to 0.5 per cent.).

7. For the relief of symptoms as well as complications, as when the process extends to the cornea forming pannus, or when vascular or ulcerative keratitis occurs, the myotics or mydriatics are indicated. Eserin (0.1 to 2 per cent.) is a stimulant of nutrition, the mydriatics are more sedative. Atropin (0.2 to 5 per cent.) is frequently indicated, especially in intra-ocular complications, but is not well borne for any length of time, as it ultimately may produce conjunctival irritation. Scopolamin and duboisin in the same strength may be substituted.

8. The relief of sequelae.—Massage is the most beneficial method of dealing with leucomata, many of which may be dissipated by conscientious daily application. Active massage is of great benefit in loosening the scars and procuring resorption of cicatricial tissue changes in the tarsal conjunctiva. The mercuric ointments or calomel, boric acid, iodoform, aristol, etc., in powder or ointment form are decided adjuvants for this procedure. Collyria, milk,¹⁸ olive oil or ointments composed mainly of lanolin relieve the symptoms caused by conjunctival xerosis.

Taking the various local medicinal applications most in vogue in the order of their usefulness, we find the silver compounds lead the list: 1 to 5 per cent.

nitrate (or iodid¹³)* of silver solutions brushed on eyelids from three to seven times a week. Its disadvantage is that it not only stains the conjunctiva if persisted in for any length of time, but is also irritating, and when used in strong solutions or in solid stick destroys the epithelium faster than the microbes, or stimulates the repair. Cases treated by nitrate of silver alone are apt to eventuate with a considerable amount of scar tissue. It is likely that the alkaline non-irritating silver compounds, argentamin^{14,22} (3 to 5 per cent.), argonin (2 to 10 per cent.) solutions may ultimately take the place of the nitrate, as they are not open to these objections, although both antiseptic and stimulating. Brushing by corrosive sublimate^{24,25,29} (1 to 1,000 to 1 to 100) has its advocates, but it is irritating and its injudicious use is open to the same objections as those of silver nitrate and it likewise corrodes the corneal epithelium. Its application should be limited to connection with surgical treatment,^{2,3,27,28,29} as scarification, expression and galvanocauterization of the follicles. Tattooing¹ with these solutions has likewise been practiced. Cyanid of mercury is better borne and not so irritating. The application of zinc solutions, such as the sulphate and sulphocarbolate are antiseptic and stimulating, but are unpleasant for the patient on account of the irritation. The solid stick of alum is a stimulant and is generally well borne. Sulphate of copper crystal, lapis divinus and muriate of ammonium should be used only for stimulant purposes (several times a week) and not with the idea of cauterizing away the granulations. I wish to here warn against the routine and discriminate use of these caustics as empirically recommended in many treatises and articles. Strong solutions of antipyrin and of quinin are advised, largely on account of their antiseptic properties. The dusting in of powders, boric acid, calomel, tannate of quinin, tannin, iodoform, antipyrin in full strength or resorcin (1 to 10 to 1 to 5 in boric powder¹¹), etc., are advocated for their antiseptic and stimulating properties, but are seldom used except when combined with massage.

The ointments of mercury (yellow oxid 0.5 to 5 per cent.), white precipitate (1 to 5 per cent.), red oxid (0.25 to 1 per cent.), calomel (1 to 10 per cent.), cupric sulphate (1 to 10 per cent.) and ichthyol (5 to 20 per cent.) are antiseptic and stimulating, especially when used in connection with massage in indolent follicular and trachomatous disease, and particularly where cicatricial tissue has formed. The value of most applications depends upon their antiseptic and stimulating qualities. Of all forms of local treatment I would consider that massage with or without medicaments is of the greatest value as it produces increase of nutrition and thus aids in resorption of the follicular contents of the trachoma bodies and of the neoplastic tissue.³⁰

Most of these applications are better borne by the patient if weak solutions of local anesthetics be instilled before each treatment. Their effect is decidedly increased if the conjunctival cul-de-sac be washed out with warm salt or boric solution. If the inflammation be attended by suppurative secretion it is well to first brush the lids with peroxid of hydrogen solution before applying silver or other medicament. It is likewise necessary to limit the action of the silver compounds by neutralization with second brushing with salt solution. The silver salts form the albuminate of silver, which lines the conjunctiva and acts

* First pass a solution (4 to 12 per cent.) of AgNO₃ over lid, then wash with mild solution of potash. R. Potass. iod., 8.00; glycerin., 8.00; aquae, 16.00, whereby a precipitate of iodid of silver is formed.

for some time after its application. The sulphate of copper crystal is to be followed by brushing with clear water to remove the excess.

I wish to here insist upon the thorough eversion of the eyelids where local applications are made to the diseased conjunctiva. The principal part of the process will be found in the fold of transmission, which can only be exposed to view and the proper application of medicines by thoroughly pushing the everted upper lid down by cotton-tipped probe or instrument.

Attention must be given to the symptoms of the patient, which should be relieved by dark glasses, hot or cold bathing and detergent washes and collyria. Medicinal applications should not be used heroically,⁴ but restricted to the indications here laid down. Many cases of follicular and trachomatous disease (granular conjunctivitis) are cured by local applications, but when adhered to alone the treatment is tedious and is perhaps more apt to be attended by complications due to neglect or over-zeal than when combined with properly applied surgical procedures by which a more speedy and satisfactory cure is effected.

THE PRESENT STATUS OF JEQUIRITY IN THE TREATMENT OF TRACHOMA.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM CHEATHAM, A.B., M.D.

PROFESSOR OF OPHTHALMOLOGY, OTOTOLOGY AND LARYNGOLOGY IN THE LOUISVILLE MEDICAL COLLEGE, ETC.
LOUISVILLE, KY.

It is my purpose in this short paper to give my

personal experience only, in the use of jequirity in the treatment of the above affection; when used in picked cases, I know of nothing that will take its place. I have used it in all cases except the acute, with nothing but the best results. I have never seen an ulcer of the cornea follow its use. I have seen some few cases of xerosis after using jequirity, but none I could say positively depended upon, or was the direct after affect of, this medication.

Several years ago one of my assistants, while squeezing a case of trachoma, was unfortunate enough to become inoculated. This case was a peculiar one from the beginning. His eyes stood no treatment well; his corneæ were extremely irritable; all the mydriatics produced increased corneal irritation; his eyes were made worse by all treatment. I compressed the trachomatous bodies twice. I had Drs. Ray and Dabney of this city to see him, but nothing suggested was of any service. I kept him in the Infirmary for months and tried every treatment I had ever heard of, with no good result. I suggested the use of the jequirity several times, but he feared it. At last I determined to use it without his knowledge. His corneæ had several abrasions, and was, as I stated before, extremely irritable. I took a small portion of the powdered jequirity, made a very weak infusion, and applied it carefully to the lids with a cotton mop, two days in succession. Little or no reaction followed, and his eyes improved very rapidly. I repeated the application three or four times. The doctor is now a busy practitioner, and suffers little or none with his eyes. He had mixed astigmatism, for which he wears correcting glasses.

I have under my charge now a case of trachoma in the person of a young woman from Illinois. She had pannus of left cornea. Just above and overlapping right cornea she had a mass of trachomatous bodies. I dusted the powder in the left eye once. The pannus of this eye was relieved promptly. Under two applications to the right eye, the mass of trachomatous bodies disappeared.

I know of no other treatment so safe that will give such results. Before expression came into use, I used powdered jequirity occasionally in cases without pannus, with none but favorable results. I have had cases with extreme pannus led into the office, unable to find their way, who under the use of the jequirity were able in six or eight days to come alone. Mary L: V. R.=P. L; V. L.=20/200. Jequirity used in both eyes. Repeated once. Ultimate result: V. R. = 20/70; V. L.=20/50.

Such cases are common in my experience. I see so many less cases now in which jequirity is indicated than I used to, because trachoma, I think is recognized earlier and treated more intelligently. Very weak infusions of jequirity are often of much benefit. But I most frequently use the powder; severe reaction is much less frequent, the application can be better confined and the powder does not degenerate with time.

The powdered jequirity I now use has been made for some years and is as active today as when fresh. I have used jequirity in all stages of trachoma except the acute with and without pannus, with none but favorable results. I am more careful now in the selection of my cases than formerly, yet I would not hesitate to use it in any case in which other methods had failed me. In select cases of trachoma with pannus, I know of nothing that will take its place.

Gentlemen who have had one or two unfortunate results from its use should try it again. I am sure they will be pleased with it if properly used, in the form of a powder, in selected cases. In some cases it is with me the last resort, in others it is the first.

THE TREATMENT OF THE MALPOSITION OF THE LID BORDER IN TRACHOMA.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June, 1-4, 1897.

BY F. C. HOTZ, M.D.

CHICAGO, ILL.

It is needless to say that the faulty position of the lid border induced by trachoma and known as *entropium*, can be treated only by operations. And it is also unnecessary to state that there is scarcely any other malformation of the human body for which a greater number of operations has been invented. Yet it is hardly reasonable to suppose that a condition so typical as the trachoma entropium could be treated with equal success by methods based upon widely different principles.

It is certainly very desirable that some order be brought into this chaos, and I believe this task is not so difficult as it may appear, if we clearly formulate our demands of what, in our judgment, a rational operation for entropium should and should not do.

The first condition we must insist upon, is that we should always take into serious consideration the cosmetic effect of our operation. The eyelids play a very important role in facial expressions, and we have no right to mar the face by unnecessarily mutilating the eyelids in the name of surgery. Every entropium operation which permanently disfigures the eyelid should be forever stricken from the list of legitimate ophthalmic operations; for the malposition of the lid border can well be rectified without the least mutilation.

The second condition we must insist upon is that the most rational method of relieving the entropium is to remove those structural changes which cause the inversion.

It is a prevalent idea that the entropium is caused by the shrinkage of the tarsal cartilage and the cicatricial contraction of the palpebral conjunctiva; and many operations are based upon this view. But that these structural changes are not the real etiologic factors in the production of entropium is evidenced by the fact that in many eyelids we find extensive cicatricial shrinkage without entropium, while in other lids we find its margin completely inverted though its tarsus is not only not contracted but abnormally large. Furthermore, it is well known that the destruction of the palpebral conjunctiva by burns does not lead to entropium, and that we may excise large portions of the palpebral conjunctiva and the cartilage without fear of producing entropium.

To trace the etiology of entropium we must study the affection in its incipient stage. And if we do so, we notice the very significant fact that the structural changes begin at the *anterior* edge of the lid margin. Long before the posterior edge shows the slightest disturbance, and even before the position of the lid margin itself is perceptibly altered, do the eyelashes show a decided drooping and the skin along their roots forms a fold falling down over and hiding the anterior edge of the lid border. In other words

the skin and the cilia have slipped down on the outside of the tarsus.

This dislocation of the skin, which is shared by the lower bundles of the orbicularis muscle, is undoubtedly brought about by continued and oft-repeated spasms of the orbicularis muscle; for it is exactly the condition of the lid margin during acute blepharospasms, made permanent.

These anatomic changes at the anterior edge persist through all stages of entropium from beginning to end and are, I believe, the chief cause of the subsequent inclination of the lid border itself; for the displaced bundles of the orbicularis muscle resting upon the anterior edge of the lid margin exert a strong pressure upon the same by their contraction in the act of winking; the lid margin will gradually yield to this pressure, become stretched and inclined when its tissues are rendered less firm and resistant by the inflammation which usually invades the tarsus in the course of trachomatous conjunctivitis.

The foregoing exposition of the primary structural changes leading to the malposition of the lid border in trachoma plainly indicates what the principal aim of our treatment should be. The dislocated skin and muscle must be drawn up upon the external surface of the tarsus and fastened to it to prevent their slipping down again; the skin thus drawn up is to be stretched sufficiently so as to turn up by its traction the drooping cilia and the inclined lid margin.

These problems are solved by the following operation: The lid skin being well put on a stretch, a transverse incision extending from canthus to canthus is made through skin and muscle a little below the upper border of the tarsus. The lid portion of the skin and muscle thus divided from the supratarsal portion is dissected up from the tarsus down to the roots of the eyelashes, and the muscular fibers covering the upper border of the tarsus are excised. The lid skin is then drawn up over the tarsus and fixed to its upper border by three silk or catgut sutures, which enclose within their loops only the skin borders of the incision and the upper tarsal border and, therefore, when tied, close the original wound and establish a firm union of the skin with the tarsus. In the five minutes allowed for this paper it is impossible to give a detailed description of the technique of this operation; nor is it necessary since I have fully described it on several former occasions.¹

Professor Schnabel² of Prague, has modified the operation by making the incision only 1 or 2 millimeters above the eyelashes, and after dissecting up the skin and orbicularis muscle to near the upper border of the tarsus, he slides the narrow strip of skin upward until the cilia and lid margin are turned up, and fixes it to the tarsus by a running suture. He wrote me that the reposition of the cilia and lid margin is always permanently achieved by this procedure, and that even in the worst forms of entropium he has no need of grooving or splitting the cartilage.

My observations on this point have led to a different result. After I had introduced the operation at the Illinois Eye and Ear Infirmary, I noticed some of my colleagues invariably made the incision as low as Professor Schnabel; but the results were so much less satisfactory than my own, that in my second paper³ I took occasion to warn against placing the

¹Prager Med. Woch., 1893.

²Archives of Ophthalmology, Vols. viii and xi; Annals of Ophthalmol. Vol. v.

³Arch. of Ophthalmol., Vol. xi.

incision too near the free edge. But in many cases the cartilage is so small that the incision has necessarily to be made very close to the cilia. And I frankly admit that under these circumstances I am not able to accomplish the complete and permanent reposition of the cilia by the above operation alone; I find it necessary to add to it the intermarginal incision and to fill the marginal wound with a graft of skin or mucous membrane. The graft should be of the same length and width as the wound. Retaining sutures are not necessary, but both eyes should be bandaged until the graft is well adherent in its new bed (twenty-four to forty-eight hours). I use skin grafts in preference to mucous membrane, because the normal lid margin is covered with skin, not with mucous membrane; because skin grafts are less liable to drying up and mortifying and because they give a more substantial support to the cilia. I cut the required strip from the integument behind the ear, the incisions penetrating obliquely just to the corium. The graft is transported directly to the lid and adjusted to the wound.

Hairs do not grow in such skin grafts. If afterward any hairs appear in the new lid margin, it is easy to prove they are cilia left behind in the posterior portion of the lid margin by a faulty execution of the intermarginal incision.

The management of entropium briefly outlined in this paper is the result of careful and critical observations and trials carried on during the past twenty years; and I feel warranted by a large clinical experience, in stating that the operative procedures here recommended satisfy every requirement of a rational operation. They do not cause any disfiguration of the lids; they rectify the primary structural changes causing the entropium; and they relieve the malposition perfectly and permanently.

HINTS ON THE HYGIENE OF TRACHOMA AND THE INFLUENCE OF ALTITUDE AND CLIMATE.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY SWAN M. BURNETT, M.D., PH.D.
WASHINGTON, D. C.

To establish efficient rules for the hygienic management of a disease it is first necessary to have definite ideas in regard to its causation, the condition of the subject and the environment most conducive to its development.

In respect to trachoma our knowledge is sadly deficient as to the majority of these factors. We have not yet arrived at the unanimous acceptance of a microbic origin of the disease. While the probabilities, in view of recent bacteriologic studies, point to the existence of a specific micro-organism as concerned in some way in the production of trachoma, the most diligent researches have failed to find one which any considerable number of investigators have agreed upon as the definite trachomatous microbe. By others it is held that the disease is essentially one of the adenoid tissue of the conjunctiva, which an inflammation of that membrane brought about by any means whatever is capable of calling up in a person predisposed to it, and who is in a condition favorable for its outbreak. In other words, a positive and well established operating course for trachoma has not yet been agreed

upon. Even its contagiousness *per se*, which was formerly accepted as one of the characteristics of the disease, is now questioned by many. It is acknowledged that the discharge from a trachomatous eye may contain micro-organisms which, when transported to another as yet unaffected conjunctiva, will set up an inflammation there, but this inflammation is not necessarily trachomatous. Any inflammation, however, is capable of setting in motion a train of processes which will end in an outbreak of trachoma if a tendency to the disease be present, just as an attack of pneumonia will hasten the appearance of tuberculosis in one predisposed to it. This matter of predisposition as applied to trachoma is one which has received considerable attention only recently. In former times it was considered a purely contagious affection to which all individuals were liable in the same degree, and this idea is still held by some.

The facts that have been elicited from a systematic investigation of the prevalence of trachoma among different people show, however, such a disparity of susceptibility among them that we are forced to consider race as an important factor in the establishment of a predisposition to the disease. Some races, as the negro in the United States, are practically immune even under the most unfavorable hygienic surroundings, while others, as the Irish, Polish Jews, Italians, etc., are especially liable and suffer greatly when there are favorable conditions for the development of the disease. With the acceptance of the theory of a dyscrasia or predisposition as probably the essential character of the affection, our ideas in respect to its hygienic management must differ somewhat from those based on the theory of its purely contagious nature. As, however, the idea of a dyscrasia has been considered seriously only within a very recent period, our knowledge of the nature of this predisposition is as yet very limited. This is a field which at present offers the most promising results for study and investigation. It must be borne in mind that here, as in all diseases of a demonstrated or supposed microbic origin, even with the acceptance of a dyscrasia or predisposition, we have to consider not only the micro-organism but also the soil in which it grows and develops. We must have soil as well as seed. A large number of pathologic micro-organisms we have always with us everywhere, and in the conjunctival sac of perfectly healthy eyes there are often to be found organisms which, if they were sufficiently numerous and the condition for their growth favorable, would in a short time set up a morbid process; all they need is a proper condition of the soil. Hitherto we have been directing our attention exclusively to the microbe, its form, habits, modes of development, etc., to the almost utter neglect of the soil on what it grows and pabulum on which it feeds. It is evident, therefore, that any system of hygienic management which aims at anything like scientific exactness and satisfactory practical results, must embrace a study of the condition of the soil on which the micro-organism grows as well as the size and shape of the organism itself. This general proposition applies to trachoma so far as it may be demonstrated to be a microbic disease. But if it shall be found that there is no specific microbe but that it is simply a disease of the adenoid tissue of the conjunctiva, there must still be something which starts the morbid process in motion, and the conditions for its action must be propitious. It seems probable that this beginning may be an inflammation of the

conjunctiva of almost any kind. Even an ordinary catarrhal conjunctivitis, the result of dust, smoke, bad air or other irritating influence, may suffice to prepare the ground and set the process going.

The first law, therefore, in the treatment of trachoma and in the prevention of it in those predisposed to it, is the avoidance of those causes which are likely to lead to such an inflammation. They should be kept apart from those suffering from any form of contagious ophthalmia. Over-crowding and badly ventilated quarters should be avoided, and such patients should be kept out of all forms of vitiated or irritating atmosphere. They should not follow any occupation in which there is dust or smoke. Out-of-door employments are not to be unreservedly recommended, since it is precisely in these that such conditions are likely to exist, especially as regards dust. This applies with especial force to general farming; for in field work of many descriptions, harvesting, threshing, etc., there is commonly a great deal of dust, while the ammoniac fumes from the ordinary farm stable are extremely irritating to the conjunctiva. For the same reason dry and dusty localities are to be studiously avoided.

The effect of climate has not yet been studied sufficiently to enable us to form a just estimate of its significance. In and of itself temperature seems to exert but little influence. Cold and hot countries are free and affected in nearly the same degree. Humidity and dryness also are not by themselves apparently of much importance since trachoma is found in both. The influence of climate would appear to depend more largely upon the presence or absence of dust than upon anything else. Of course the habits of the people in regard to over-crowding, etc., as influenced by climate are not without their effect in this particular.

As a rule the countries bordering on the sea are less affected, probably on account of the absence of dust, while the interior lands, subsequent to long drouth, are afflicted more seriously. Some of the most malignant cases we have in the central portion of this country are to be found among the inhabitants of the country districts of Kentucky and West Virginia. Further investigation is much needed on this point, and it is hoped that observation will in future be more specifically directed to the meteorologic conditions as influencing the development of this disease.

The same may be said of altitude, for we have found that altitude alone does not give an immunity. It is seen at the height of 10,000 feet above the sea-level in Colorado and in the mountains of the Tyrol, and I have seen it among the mountains of East Tennessee 1,000 feet. On the other hand certain countries at the sea level as Ceylon are entirely free. It would seem to be a fact, however, that other things being equal a high elevation, if not dusty, exercises a beneficial effect on the course of the disease, most probably on account of its bracing effect on the general system.

TEN YEARS' EXPERIENCE WITH THE SURGICAL TREATMENT OF TRACHOMA.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY HAROLD GIFFORD, M.D.

OMAHA, NEB.

Although the idea of treating trachoma surgically is at least as old as the days of ancient Greece, it received very little attention in modern times until

about 1890. To be sure, occasional writers, Galezowski, Mandelstamm, Schneller, Hotz, Prince and others, had urged upon the profession one surgical procedure or another, but when I first began to devote myself to ophthalmology in 1882 and for eight years thereafter, surgical measures had practically no place in the treatment of trachoma in a great majority of clinics in this country and in Europe. In the years 1890-92, however, ophthalmology suffered from what amounted almost to an epidemic of surgical cures for trachoma, and cutting, brushing, burning, scraping, squeezing and scarifying were recommended with an enthusiasm born of incomplete observation and hasty generalization. Nearly all of these methods were warranted to cure the great majority of cases in from one to four weeks and the prospects opened up to the general practitioner and to the oculist with a number of old trachoma cases on his hands, were so brilliant that it is not surprising that bluestone and nitrate of silver went to a discount, while Knapp's roller forceps and other mechanical appliances rose in favor correspondingly. Those, however, who had for several years previous to this epidemic been treating trachoma by surgical methods knew that these high expectations would not be fulfilled and that a reaction was inevitable. The signs of this reaction are now apparent enough and I think it not unlikely that unless the good which can be accomplished by surgical measures be urged systematically and with moderation, in fifteen years they will have no more of a place in ophthalmology than they had ten years ago. The trouble with these methods is that while each of them can do some good, no one of them is applicable to all sorts of cases, and it is even rare that any one of them is sufficient for any given case.

I began treating my trachoma cases surgically in 1886, and while the brilliant results which at first I thought I secured afterward, in many cases, turned out to be only moderate, I have persisted in the use of squeezing, cutting, scraping, burning and scarifying, each in its proper place, combined, nearly always, with applications of nitrate of silver and sulphate of copper, and have learned to make use of them in many cases in which, by some authorities, they are considered contra-indicated. The only cases in which I consider them, as a rule, contra-indicated are those of acute trachoma; for the great majority of these, if seen within a few days from the start, can be cured in from three to six weeks (and occasionally in much less time) by a thorough daily application of the sulphate of copper crystal to the retrotarsal folds. When at the end of the latter period there are still marked signs of infiltration, the use of expression or the excision of a strip from the folds is generally indicated.

With regard to the technique of expression, I use forceps, to be described later on, going over the tissues at least three times, with gradually increasing pressure. In this way the trachomatous foci are first broken up and then thoroughly squeezed out, without so much tearing of the folds as sometimes results if the attempt is made to squeeze them out completely at once. To prevent the adhesions which otherwise often give much trouble in the after-treatment, I have of late, at the close of extensive operations, everted each lid by two stitches, which are passed through the edge of the lid and the skin of the cheek or brow. A moist dressing is then applied, the moisture being retained by gutta-percha tissue and the cotton which comes next to the everted lids being well coated with

sterilized white vaselin. This and the stitches are removed permanently after twenty-four hours and by that time the abraded surfaces are so thoroughly glazed over that there is little or no subsequent trouble with adhesions. In some cases where the dense non-gelatinous nature of the infiltration of the folds and the edge of the upper tarsus indicate that expression alone will not get rid of the trachoma quickly, I combine expression, excision and sharp curetting at the first operation; the gelatinous portions of the folds being squeezed, the rest excised and the tarsi well scraped. With regard to the technique of excision of the folds, I use none of the clamps which have been devised for facilitating the operation, but simply raise the everted fold with a fine-toothed forceps and excise as broad a strip of it as seems necessary; and in the case of the upper lid I generally cut out from the central edge of the tarsus a strip from one-twelfth to one-eighth of an inch in breadth. I have never felt like going as far in this direction as Heisrath (*vide* Lehmann, "Inaug. Diss.," Königsberg, 1895) who, in many cases, excises nearly the whole tarsus, leaving only a strip 1 to 2 mm. in width at the ciliary margin; though I have no doubt that, in many cases it is an excellent method of getting the patient into a tolerable condition; and from what I have seen of one of his cases, it produces none of the bad results which, *a priori*, one might expect to follow so radical a procedure. Where the strip excised is narrow and includes little or none of the tarsus, no suture is required, a few days bandaging is enough; otherwise, I close the wound with a continuous suture,

Trachoma Forceps.

starting and finishing at the extreme ends of the lid, so that the knots are left on the skin side. This I consider important, because the knots of interrupted sutures are apt to irritate the cornea. I have seen one case in which serious ulceration was started by them and that this is not unusual I judge from the remark of Lehmann (*loc. cit.*, p. 12) who, in reporting Heisrath's excisions, naively remarks that if the patient complains of much pain it is best to remove the bandage and see if the sutures are not causing ulceration of the cornea.

The squeezing out of gelatinous matter can be accomplished with greater or less facility with any of the various forceps invented for this purpose. The original ring forceps of Prince is very efficient, and Noyes' stocking forceps has advantages in certain cases. One of the best all-round forceps was devised by my former colleague, Dr. Graddy, now of Nashville, Tenn. Knapp's roller forceps, though ingenious in principle, are not so useful, in my opinion, as any of those just mentioned. They can only work in straight lines, which makes them very unhandy for working in the pockets at the extremities of the lids; and the rollers are necessarily so thick that if the conjunctiva is atrophic, the infiltrated areas often can not be grasped by them. In the forceps which I use, I have had combined the advantages of the ordinary ring forceps, the strength and breadth of blade of Graddy's instrument, and at one portion of the ring, the narrow edge of Noyes' stocking forceps. In certain old cases

with much atrophy of the conjunctiva, one not infrequently sees areas of infiltrated tissue in the corners, which can not be seized and properly expressed with any other forceps that I have seen. The butt end of this forceps is made of a single piece of rounded and thin-edged metal, thus forming a very useful instrument for squeezing, between it and the fingers, portions of the tarsi which can not be seized to advantage with the forceps blades.

Cases of old and so-called cicatricial trachoma are by many excluded from surgical treatment; but these are just the cases where it is of infinitely greater benefit than any form of medical application. Here, besides expression and excision, scraping with a sharp spoon, the actual cautery and scarification, followed by some medical application, are of the greatest value and will often produce the most rapid kind of cures. Occasionally the procedure of Noisewski, namely, the deep excision of the diseased tarsal conjunctiva with grafting of lip membrane to replace it, is in order. I have tried it with good results in a few cases where the disease was so deep-seated that nothing but excision or the deepest kind of scraping or burning would remove it, and yet the membrane was so atrophic that practically no lining for the lids would remain after such measures, unless grafting were done. The use of the actual cautery I generally limit to cases in which small, deeply infiltrated islands of trachoma occur. Where these islands are larger I use the sharp spoon or scarification. Brushing seems to me to be a very crude and inaccurate method.

In nearly all cases, except the acute ones, some sort of surgical interference is called for more than once, and in the intervals between the surgical proceedings, the application of sulphate of copper, nitrate of silver or some other astringent or antiseptic is called for; and in many cases all the surgery which I think it safe or advisable to use upon the lids does not prevent the necessity for many months of medical treatment. I have spoken of sulphate of copper and nitrate of silver as equal in efficiency, but on account of the great advantage which copper possesses in not staining the tissues it is the only application which I recommend for a long continued use. The staining caused by silver is a disadvantage not merely from a cosmetic point of view, but because it renders intelligent treatment much more difficult by disguising the line between healthy and diseased tissue.

Finally, a word as to the dangers of the surgical treatment of trachoma. Some years ago I wrote a paper on this subject, in which reference was made to two cases of my own in which the cornea had been somewhat injured by ulceration following the use of surgical measures: while in the case of four other eyes, in the practice of other physicians, sight had been completely lost from a similar cause. Since then other writers have reported unfortunate results of the same sort and have confirmed me in the conclusions at which I then arrived, namely, that while the surgical treatment of trachoma is of great value in nearly all classes of cases, for the majority, it is not a swift and unfailing cure (unless we include follicular conjunctivitis); and where there is non-vascular ulceration of the cornea, its use may be attended with the most serious danger to sight. If I had to choose between the exclusive use of either the medical or surgical treatment of trachoma, I should certainly choose the medical, for with it nearly all cases can be kept from injury to the sight; and most cases can in

time be cured. The surgical treatment is of great value, but I seriously question whether in inexperienced hands it will not in the long run, do much more harm than good; for not only is there direct danger to the cornea in some cases, but where relapses occur after its use, I have a decided impression that the disease gets a deeper foothold in the tissues and is more apt to cause ulceration of the cornea than when medical applications alone have been employed. Instead of simplifying the treatment of trachoma, the introduction of surgical measures has decidedly complicated it, and no one should use them who is not thoroughly versed in the diagnosis and treatment of all diseases of the conjunctiva and cornea.

TRACHOMA, ITS RELATIVE INFREQUENCY IN SOUTHERN CALIFORNIA.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY H. BERT. ELLIS, B.A., M.D.
LOS ANGELES, CAL.

Although there is not a perfect agreement among pathologists as to the identity or non-identity of follicular conjunctivitis and trachoma (that is, as to whether they are independent affections), still the recent text-books on ophthalmology are almost unanimous in making a clinical if not a pathologic distinction between these manifestations. It is not my intention, nor is it necessary in a paper of this description, and on such an occasion, to enter into a dissertation giving the details of the arguments that have been, and are still being brought forward to prove the sameness or dissimilarity of these diseases. It is sufficient for the purposes of this article to state my own position in the controversy without giving the reasons for "the faith that is in me," and thus prevent any misunderstanding of terms.

"Granular lids" is a phrase that I but rarely use, and then always as a synonym for trachoma (Dr. Burnett to the contrary notwithstanding), a specific disease ordinarily depending on the transference of secretion from some other affected eye. Follicular conjunctivitis I believe to be entirely independent of the former, and not an early manifestation or stage of trachoma, but as in many other clinical conditions, differentiation is not always easy and both diseases may be present in the same eye at the same time.

As oculists we must all realize that to the laity all roughness of the conjunctive is, and all sandiness and smarting the result of, "granular lids." To what extent the general practitioner is accountable for this view I do not know, but I fear his responsibility is great; and I think that as a society and as individuals we should use every endeavor to correct this false, or to speak the best for it, this imperfect view. It seems to me that the terms "granular lids" and "granular conjunctivitis" should be eliminated from our vocabulary as not being scientific, and because they serve no useful purpose, but on the contrary tend to confusion.

In order that this paper might not express the views of the writer alone, and in order to know what the other oculists of Southern California thought concerning the relationship of these diseases, I sent the following questions to the leading eye men in Los Angeles and the surrounding country from Bakersfield in the North to San Diego in the South:

1. Do you make any distinction between follicular and granular conjunctivitis? If so, what?

2. In your ophthalmic practice in Southern California have you observed granular conjunctivitis (trachoma) frequently? In about what percentage of your cases?

While these questions were not designed to cover the field of the pathology of the diseases under consideration, they were sufficiently comprehensive to discover the manner in which the different men used these terms, and by this means I believe I have been able to quite accurately substantiate the inference of the title of my paper, that is, that trachoma is relatively infrequent in Southern California.

I tabulated the replies of the best known oculists in the southern portion of my State, and it was worthy of note that nine out of the ten differentiated between the diseases; that but one said there was practically no difference, and even he found only 1 per cent. approximately of both conditions together.

There were nearly as many ways of distinguishing between the affections as there were replies to my inquiries and the summary would seem to indicate that the differential diagnosis was not sufficiently clear to each one of the writers, as to make it possible for me to believe that each of the oculists was always absolutely certain of his diagnosis. However there was sufficient similarity and unanimity to show that the broad distinctions were concurred in by most of the writers. Nearly all considered trachoma or "granular lids" a specific disease, in all probability contagious, occurring principally among the poor who live in crowded and filthy localities. Follicular conjunctivitis might or might not be contagious, occurring more frequently among the "well-to-do." Trachoma always leads to the destruction in a greater or less degree of the conjunctival tissue, while the follicular trouble may exist indefinitely and yet result in no loss of conjunctiva. Every one replied that trachoma was relatively infrequent in this section of the country. The percentages varied from 0.5 of 1 per cent. to 2 per cent., with the exception of one which was 5 per cent.; but the man who gave this report had been here but a year, and remarked that most of his cases were chronic and imported from the East.

In my own practice, extending over a period of eight years in Los Angeles, I have had less than 1 per cent. of trachoma, including both my private work and college clinic, and the cases were about equally distributed among the poor and wealthy. Follicular conjunctivitis I have found relatively more frequent, but these cases do not reach higher than 5 per cent.

Why trachoma should be relatively infrequent in Southern California I do not know, but the statement of a few facts may throw some light upon the subject. We have a cosmopolitan population; the Irish, the English, the Scotch and the German; the Frenchman, the Italian and the Spaniard; Jews from all countries, negroes, "Japs" and Chinese, but mostly Americans. But the trouble is not confined to any particular nation. In no part of our city are the inhabitants particularly crowded. The great bulk of the population lives within twenty-five miles of the ocean and at an elevation of less than 1,000 feet. The climate is such that an out-of-door life is the rule. This fact with our relatively good sanitary conditions, helps to render our poorer citizens comparatively healthy and so they are enabled to resist, or rather they are rendered less susceptible to contagion of any kind.

THE SURGERY OF TRACHOMA.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY S. LEWIS ZIEGLER, M.D.

OPHTHALMIC SURGEON TO ST. JOSEPH'S HOSPITAL,
PHILADELPHIA, PA.

Surgical procedures for the relief of trachoma are only indicated in the chronic stage of this disease, and especially for the relief of the complications and sequelæ, the most common of which are pannus, ulcerative keratitis (chiefly in the form of multiple erosion ulcers), blepharophimosis with its accompanying lid friction, and mucopurulent discharge or epiphora. A more remote sequela is the contraction which results in ectropion, or entropion with trichiasis.

Without going deeply into the subject of the *etiology* of trachoma, there is no doubt but that the essential elements in its *persistence* are, a partial occlusion of the tear duct, with consequent epiphora and regurgitation of septic secretions; a perversion of the ocular secretions themselves; the maceration of the cornea from the excessive amount of secretion and discharge present, and finally friction from tarsal pressure, with erosion of the corneal epithelium.

In the first place we can definitely assert that the persistent growth of the graulations which have already formed is kept up by the continued moisture present, together with the irritation of the septic secretions, just as polypoid growths increase in the presence of moisture. Furthermore, the tear-duct, even if it were not originally at fault, through participation in the inflammation and subsequent contraction, with a like perversion of the secretions contained within its lumen and the partial abolishment of its capillary action, due to its thickened mucous lining and viscid contents, not only prevents the tears from passing downward, but really adds to the trouble by the constant regurgitation of these septic secretions; in fact, not infrequently the local inflammation has gone so far as to have broken down the lining membrane of the tear-duct and involved the bony canal itself.

Manifestly then, the first object to be accomplished is to secure a patulous tear-duct, by means of *rapid dilatation*. It has been my custom for several years past to accomplish this without any incision of the tissues, as the latter only leads to subsequent cicatricial contraction. This is done by first introducing a needle-probe into the lachrymal puncta and passing it through the cartilaginous canal; it is then withdrawn and a conical dilator¹ with a maximum size equal to that of a No. 10 probe is passed through the cartilaginous canal, and thence through the bony canal into the nose. It is seldom necessary to repeat this procedure in order to maintain a patulous duct, but occasionally there will be sufficient contraction to require a second dilatation. By this method, without incision, the capillary action of the duct is retained and the current of lachrymal drainage directed downward toward the nasal orifice.

The second procedure is the operation of *canthoplasty*, to relieve the friction of the lids, and, at the same time, the tendency to maceration, which is an unavoidable accompaniment of this condition. This operation should be a more extensive one than that usually employed; in other words, a simple section of the external canthus with the scissors will not give sufficient relief to accomplish our purpose. The section

of the lids having been accomplished with a pair of strong curved scissors, with the curve turned upward to correspond to that of the upper lid, a section of the external canthal ligament should follow, which can best be accomplished by grasping the end of the incised upper lid with a tenaculum or strong rat-tooth forceps and exerting slight traction, in order to make tense the superior canthal ligament, which is then cut with a pair of small scissors as near to its bony attachment as possible, in order to avoid any traumatism of the lachrymal gland. Sutures are then inserted in the usual manner, the conjunctiva and skin being brought together neatly.

Ordinarily if these two procedures are thoroughly and boldly performed but very little other treatment will be required, unless there is still some regurgitation from the tear-duct, in which case the nasal condition on that side should have some sedative treatment, and if, as is frequently the case, there are adenoid vegetations present operative measures for their removal should be at once undertaken. For the relief of the granulations themselves, slight scarifying of the lid, followed by the use of Knapp's roller forceps will usually accomplish all that is desired. If, however, hypertrophy is still persistent, electrolysis as suggested by Dr. Johnson, or the galvano-cautery may be required to reduce the exuberance and hasten resolution.

Certain other measures have been suggested from time to time, but do not appear to have the value that those outlined have shown to possess. Burow's operation, consisting of an incision of the superior tarsal cartilage along the whole inner margin of the lid, thus making a flail-like hinge, does not yield any more freedom from blepharophimosis than an *ordinary* canthoplasty, and by no means as much as canthoplasty combined with section of the superior canthal ligament. The operation of peritomy or syndectomy, consisting of a section of the blood vessels around the limbus corneæ, is not always successful in stopping this vascular invasion, and I have never found it necessary in cases where rapid dilatation and canthoplasty had been performed.

The local treatment to be applied to the mucous membrane itself should be of a mildly astringent character and not sufficiently irritating to keep up the disturbance. Tannin and glycerin may be applied every day, or on alternate days, while the nasal disturbance is best relieved by applications of tr. benzoin comp., which is antiseptic, astringent, depleting and stimulating. The multiple erosion ulcers generally disappear as soon as the friction and maceration have yielded to the treatment that has just been outlined. The relief from friction, pressure and maceration and the free drainage of the septic secretions seem to promptly bring about resolution and hasten convalescence.

1509 Walnut Street.

DISCUSSION ON TRACHOMA.

Dr. HERMAN KNAPP of New York. I did not hear the paper of Dr. Weeks but as regards the treatment of trachoma we have certainly to distinguish two kinds of trachoma clinically, which I would like to call non-inflammatory or simple, and inflammatory. I meet in New York a relatively large number of cases where there is no trace of inflammation visible. Sometimes the discovery is made accidentally; when the lids are turned, the upper and lower retrotarsal folds are found more or less completely studded with granules. In the course of time, and by unfortunate circumstances, those granules will produce irritation and inflammation of the catarrhal kind, and so we get the mixture of pathologic condition which we call in-

¹ The dilator is the writer's modification of the one devised by the late Dr. Lewis. It is made by Gemrig & Son.

inflammatory trachoma, and this is certainly contagious, as the reverse process may take place just as well. These two conditions indicate different methods of treatment. For the simple granules, which may be excessively numerous, with no inflammatory symptoms, I know of no better remedy than the surgical treatment with some kind of forceps. I saw Dr. Noyes use his forceps, and I thought that a forceps that would be equally efficient in removing the granules and more saving with the tissue would be best, so I made the roller forceps. I do not go over the surface once or twice, but repeatedly, and with always a moderate amount of pressure. This I do in all parts of the conjunctiva. Nothing should be omitted. In the majority of cases medicinal treatment is necessary; there is only a relatively small number where surgical treatment alone will produce a cure, but it is possible for them to get well by surgical treatment, and I have in mind even that they will get well without treatment, but this I can not very well ascertain from personal observation, for I have never allowed myself to send a patient home and then watch him for a year. It would be, however, a permissible experiment. As for after-treatment, I mostly use sulphate of copper, applied every day and very mildly, but especially in the posterior retrolarsal folds.

I am quite in accordance with Dr. Burnett that the cleanliness of the atmosphere has a great influence on the treatment, just as it has on the production of the disease, for I know patients that I can take to a well-ventilated hospital, unlike their crowded homes, get well in a shorter time and show generally better results. When the patients go home it is necessary to watch them, because relapses, though in the minority, are not infrequent. If they expose themselves to an impure atmosphere they will have the same conditions and reproduce the disease.

With regard to the harmfulness of mechanical treatment, and especially the roller forceps, I am astonished to hear of the destruction of the cornea. I do not remember one single case where, by the roller forceps, a corneal ulcer was produced, or an existing one aggravated. In no case was there any such thing as sloughing, and I think that must be entirely accidental.

With regard to adhesions, I have seen two cases; I mean not of one part of the conjunctiva to another, but to the eye ball, symblepharon.

Dr. GIFFORD—I referred more particularly to adhesions in the conjunctiva of the lids.

Dr. KNAPP—I think the retrolarsal fold shrinks and gives the impression of adhesions, but it never distorts the lid at all, and I think we need not be afraid, on that account, to use the forceps. I would like Dr. Gifford, in closing, to explain more fully about going into the cicatricial conjunctiva to find trachoma foci; I have had no experience with it.

Dr. HAROLD GIFFORD of Omaha—With regard to Dr. Würdemann's paper, I disagreeless with him that I expected to. I was expected to "rip him up the back," but I find small chance to insert the knife. I am in accord with him fully on the pathologic process so far as the microscope is concerned. I do not think you can distinguish with the microscope between trachoma, the papillary condition after gonorrheal conjunctivitis, and some forms of follicular catarrh. I have the best reasons for believing that trachoma is a contagious disease, for I contracted it myself from squeezing a granule and having a drop fly into my eye; I had the disease for two years. I have cases in which I wish for something new every now and then, but I have not branched off from the old treatment of silver and sulphate of copper, and the latter is my main reliance. After reading the original communications in which such good reports were made for argenticum, I sent for some of it and treated one case by applying argenticum to one lid and nitrate to the other, but I was disappointed to find that the former had less effect. Whether it will eventually stain the lids remains to be seen.

As to the method of treating cicatricial trachoma I do not wish to be understood as saying that where trachoma has run its course in certain portions of the lid you can take those portions and squeeze any matter out from them, but in all my cases I only know of one exception, in thousands of cases which I have treated, where I could not find undoubted foci of trachoma thickening. You would see some thickness, and on squeezing get quite a bubble of gelatinous matter. I was surprised to find it so. Where everything is atrophic there is no use in squeezing. This condition may keep up continuous ulceration of the cornea. It is found particularly toward the inner side, and by turning out this little area and burning it with the cautery, or scrape it out (I prefer the cautery), I have been able to cure them within a minute or two.

Before finishing I want to pay a tribute to Dr. Hotz's contribution to the treatment of trachoma. In the first place, his method of squeezing out the follicles with the thumb nails was

a decided advance, and while I do not think it is the proper method to continue now, it served to call the attention of the profession to the treatment. Dr. Hotz was the first man to insist on the method of pressing back the globe to force this fold of tissue into view. In regard to the treatment of the edge of the lid, Dr. Hotz described his method of putting in a skin flap in addition to his original operation. I am not prejudiced against the use of skin, for I was one of the first to suggest the use of the Thiersch flaps. I found a great many cases where the entropion would be cured entirely, but a little of this skin would be turned in to rub the cornea and while in many cases it produced no irritation, in some it did and made me want to get it out. So I use skin no more, but mucous membrane almost entirely. If you put skin into the undersurface of the lid it stays skin, and does not become mucous membrane. You can scrape up rolls of epithelium with the nail for a long time, and it also collects there to decompose and produce irritation.

Dr. FRANK ALLPORT of Chicago—I have been much interested in the discussion of trachoma and its consequences. The subject appears to have been quite thoroughly exhausted and there remains but little to be said. Dr. Hotz's idea of the cause of entropion is certainly very seductive and plausible, and while I believe entropion to be frequently produced by contraction of the tarsus and conjunctiva, yet I have seen many cases where a dislocation of the soft portions of the lid covering the tarsus was the only evident pathologic condition. Dr. Hotz has so long been regarded as an authority on the subject of lid surgery, that I think but few of us would have the temerity to question any statement he might make, and I have nothing but praise to say of his operation for entropion, which I have used for some fifteen years with thorough satisfaction. I sometimes vary the operation by a canthoplasty or a transplantation of tissue into the lineal gaping wound along the margin of the lid, or the removal of a piece of cartilage from the face of the tarsus, or even the removal of some skin in people possessing very redundant lids; but Dr. Hotz's operation as described by him many years ago and reiterated in the paper which we have listened to has formed the basis of all of my entropion operations for many years, and I have never had reason to regret my allegiance to this procedure. By using the tip of the tarsal cartilage as a fulcrum upon which to evert the palpebral margin we have a firm and substantial point upon which we may depend, and therefore the operation is built upon a sure foundation. The mistake is sometimes made of making the cutaneous incision a little higher than the tip of the tarsal cartilage. In this event we will not secure the full benefit of the operation, as it is necessary that the incision should be nearly on a line with the tip of the cartilage or a little below it in order to evert the marginal lashes. I have known operators to discard Hotz's method where the cicatrix plainly showed that the line of incision had been too high, and consequently practically useless. Concerning the objections to Dr. Knapp's roller forceps, I have only to say that I have used them with thorough satisfaction for a number of years and have never seen any of the accidents to the cornea which have been reported as following their use. I can not but believe that the abraded or ulcerated cornea that some gentlemen report have been due to a careless use of the instrument, which is more or less bulky, and may very easily abrade a cornea unless due care is taken. In using the instrument, I think the patient should first be thoroughly, generally anesthetized, as the operation is very painful, and the cornea may easily be injured during the struggles of an unanesthetized patient. The lid should then be gently but completely raised from the eyeball before the roller forceps are put in place, and this idea should be observed during the whole course of the operation. The expression of the trachomatous granules should not be done with the vigor which I have sometimes seen used. The forceps should be gently and repeatedly rolled, or milked, over the conjunctiva, which will produce in time a thorough evisceration of the granules without the tearing and stripping of the conjunctiva which is complained of by some operators. I believe if Knapp's roller forceps are used in this way they will fulfil the purpose of any forceps designed for the evisceration of trachomatous granules. After the granules have been thus expressed, a wealth of valuable and reliable methods of treatments may be adopted, and it is well to change the treatment from time to time. For several years I have been especially wedded to the boric acid powder, profusely dusted upon the everted lid and vigorously rubbed into the conjunctiva with the tip of the finger. This treatment is especially adapted to those cases of trachoma complicated with the various forms of keratitis, and although very efficient is *not irritating*. I have also lately used with much satisfaction a 1.5 per cent. solution of the pure iodine crystals in oil of vaselin freely daubed upon the lid by a camel's

hair brush. These two methods are merely suggestions which I have found valuable in my practice when I desire to change from the old orthodox copper and nitrate of silver applications. As I have seen some operators who have sustained infection from the spattering of the trachomatous granules into their eyes during an expression operation, I would beg leave to suggest that as a matter of self protection we should use large isinglass eye-protectors while performing such operations.

Dr. S. LEWIS ZIEGLER of Philadelphia—In regard to Dr. Knapp's forceps, I use a much shorter and thicker roller than I have seen here, because I can get into the folds so much better. In using them I draw them *diagonally* across the lids instead of straight up and down, and in that way do not pull so hard on the retrotarsal fold. There is very little reaction following this procedure, but where it does occur ice compresses will relieve it. I believe that no matter what the original cause of trachoma may be, the tear-duct has a considerable influence not only in the initial stage but continues as a disturbing factor at all times.

Dr. F. C. HOTZ of Chicago—I was very much interested in what Dr. Gifford said regarding the isolated foci in the cicatricial stage, for it fully tallies with my own observations; I have many times seen this. When the lid looks perfectly smooth we may on careful inspection find these little foci. Another matter of importance to scrutinize is the condition of the Meibomian glands, which often lead to the formation of small pus foci in the lid; these ought to be punctured. I was rather surprised to hear of the danger of adhesions forming in the retrotarsal folds. I have to relate that existing ulcerations have not been aggravated, and squeezing out the follicles never produces them, but on the contrary the beneficial effect of the mechanical removal of the follicles upon the inflammatory processes of the cornea, I have often remarked; within twenty-four hours I have seen the most irritated eyeballs become quiet and the inflammation of the cornea subside. I have never seen adhesions, and I wonder why it is. I can only account for it, by the different methods and probably different instruments used. It has been mentioned by Dr. Gifford that I suggested using the finger-nail for squeezing the follicles. That might give the impression that I picked out the follicles, which is not correct. The way I do, and which I still regard as the most gentle way of evacuating the follicles in the upper lid, is to evert the lid, press the eyeball back, and while the thumb is on the everted surface of the lid the thumb of the other hand is placed under it, and you have the pressure of the two through the lid upon the fold, and the follicles can be evacuated, and you can gauge the pressure better by the fingers than by any instrument. On comparing the different forceps, I find that many of them have blades which when closed form almost scissor blades, and some are curved so that the conjunctiva is locked up in them, and when traction is made it is no wonder that laceration results. If the forceps blade is curved and absolutely rounded so that by the strongest pressure even the conjunctiva can not be held, extensive laceration can not occur. I would like to make one remark in reference to the implantation of skin in the lids. Dr. Gifford said that skin remains skin, and that is true, but if he says that desquamation of the skin continues and acts as an irritant, I beg to differ with him. I have never seen any irritation in my cases, and I have noticed after implanting skin-grafts, in cases of pterygium, that this desquamation ceases and the tissue looks smooth as conjunctiva, and you can scrape off no cells.

Dr. A. C. CORR of Carlinville, Ill.—I have a mental obliquity that makes me unable to see that trachoma is a disease of itself and of its own kind. I have seen nothing to convince me, and am not fully persuaded that it is so. I think it is a pathological condition growing out of a progressive inflammation of almost any kind. The follicular process is a diseased condition resulting from various causes (reading from manuscript). It was with great gratification I heard Dr. Knapp say that he had seen cases where no inflammation had preceded. I have everted the lid of persons who did not suppose they had any trouble with the eyes and discovered these sago-like grains. If you turn down the lower lid of many school children you will find the first stage of the follicular conjunctivitis, and it may get well without any treatment at all. If it goes on it will produce the condition you are familiar with, and I think may lead to thickening and chronic trouble.

Dr. G. C. SAVAGE of Nashville—It would be well to go into the history of Dr. Gifford's own case; I have that history. At the same time that the Doctor's eye was infected his associate got some in his eye. The latter at once had instilled a 10 gr. solution of nitrate of silver. He did not develop a case of trachoma, and Dr. Gifford did. We had a similar example a few years ago. Dr. Price got some of this material in his eye. I gave him nitrate of silver immediately and he did not de-

velop trachoma. That leads me to say that Muttermilch is not far from being right when he says that the germ is to be found early in the epithelium, and if we have some remedy to go into the epithelium and destroy them all will be well. We have a remedy that will destroy the epithelium, that is nitrate of silver. Acetic acid might be expected to cure them before they get into the epithelium. I have used silver in the strength of 120 gr. to the ounce and quickly neutralized it by potassium iodid. The first case of this kind occurred as an accident. I have entirely given up the use of sulphates in the treatment of conjunctival troubles, because I think I have in the acetates a class of remedies that accomplishes just as much without doing any harm.

Dr. H. V. WÜRDEMANN of Milwaukee—It is impossible to fully discuss this subject upon which many of us might write a volume, so I shall only take up a few of the points. It is certain to my mind that trachoma is a condition that supervenes upon a number of different irritations that might be caused by different infections. It is a condition largely brought about by mechanical irritation of a dust-filled atmosphere. In the Northwest we have a large foreign population, and we have the conditions in some portions of the country depending upon the atmosphere entirely. Our confrère, Ole Bull, states that he has seen but three or four cases of trachoma in his part of the country, although the condition of the peasantry is deplorable. He remarks that in his country washing and changing of the underwear is believed to be an unnecessary luxury, but even there he has seen very little trachoma. In regard to the use of powders, etc., I beg to remind Dr. Gifford that argenta-num is of less strength than silver nitrate, and that comparisons should be made with comparative strengths. The principal point I want to bring forward is, that in local applications it is necessary to bring the fold into view and make the applications to that. Where the small hard granules appear they may be readily destroyed by the galvano-cautery. Burchard has made over three hundred and sixty applications to a single lid in several sittings, in many of them making fifty to one hundred punctures, and the cases have been cured.

Dr. S. M. BURNETT of Washington, D. C.—I am sorry to hear so little said in regard to the hygienic treatment in the care and prevention of this disease. However gratifying to our vanity to perform brilliant operations, we must remember that in our profession it is a higher function to prevent than to cure disease. In order to prevent a disease it is necessary to know its natural history, and we should know the conditions of the individual and his surroundings. It seems to me that part of this subject has not been thoroughly studied. The time is coming when we should give more attention to the matter than we have in the past. It is only by collective investigation that we can study this in reference to the race, climate and habits of life and the conditions that surround the patient at the time of the development of this disease. When we do that we shall enter upon the performance of our highest duties as medical men.

Dr. A. E. BULSON, JR., of Fort Wayne, Ind.—One thing that interests me particularly is the question as to whether this disease is contagious. An instance that occurred to me has led me to believe that it is transmissible, and I will report the case. I attend an orphan asylum, located in a high and dry portion of the city and possessing good sanitary conditions. About two years ago my attention was called to a well-marked case of trachoma that had come into the institution a few days previously. I immediately informed the assistants to watch the case and keep it practically isolated, for otherwise we would have trouble with more cases. The advice was not heeded and we soon had a typical epidemic of trachoma in the institution. We had 165 cases and the last of them is not over yet. Those cases I consider all developed from the one child. It is not a dusty locality nor a dirty one, and the children are kept as neat and clean as possible. The treatment of these cases consisted principally of the use of Hodge's mixture, advocated by this Society in 1887. Some of the cases, eleven or twelve, were operated upon with Knapp's forceps. In a few of the cases powdered boric acid was used and I was favorably impressed with its action.

Dr. A. E. PRINCE of Springfield, Ill. Taking up Dr. Hotz's paper first, I would speak with reference to the line of incision. I commenced practicing the operation for intumed lids by making the incision recommended by Dr. Hotz, but I soon lowered the incision until I came to within 3 mm. of the lid margin. I did this almost without knowing it, and on one occasion, while reviewing the papers of Dr. Hotz, I found a footnote in which he described the operation of a Greek surgeon, and I found that I had been doing that operation. Dr. Knapp has called attention to the non-inflammatory trouble. I have seen three cases. In all these cases it disappeared without surgical treatment, and I think in such cases the

indication is not to operate. I have not seen the adhesions spoken of and I attribute it to the fact that the instruments I use have sharp edges, some of them almost scissors-like, as has been mentioned, and in the next place I apply cocaine to prevent pain. I take a 10 per cent. solution, saturate a pledget of absorbent cotton, place it upon a piece of rubber tissue and slip that up in the retrotarsal fold and closing the lids leave it there for ten minutes. The cornea is protected, the cocaine soaks into the lid and you can do the operation without any material pain.

SUBCUTANEOUS INJURIES OF SOFT PARTS.

BY JOHN EDDY LUCKEY, M.S., M.A., M.D.
VINTON, IOWA.

AWARDED THE J. W. FREER SECOND PRIZE, RUSH MEDICAL COLLEGE, 1897.

(Concluded from p. 62.)

SUBCUTANEOUS INJURIES OF THE ABDOMINAL ORGANS.

The stomach, when of normal size and in its proper position, is so well protected that it is seldom injured by non-penetrating forces. Contusions, laceration or complete rupture may result from a blow or kick, administered over the organ, when in a state of partial or complete distention. Violent emesis has caused rupture of the stomach in cases already weakened by constitutional or local disease. In O'Farrell's¹⁴ case violent vomiting, during fever, caused a rupture of the posterior wall three inches long. Owing to the greater thickness of its walls and its better protection, the stomach is less frequently the subject of rupture than is the intestine. Other viscera are generally involved and the injury is, as a rule, fatal. The seat of the rupture is usually near the pylorus, or greater curvature, though it may be in any part. Morris's¹⁵ case had a tear one and one-quarter inches long in the middle of the great curvature. Gaunett's¹⁶ case had a vertical rupture, almost completely dividing the stomach. Elliot (July, 1895) found a linear tear in the anterior stomach wall, with rupture of the duodenum, caused by the kick of a horse; these wounds were sutured, but death followed, leaving, however, no traces of peritonitis.

Symptomatology.—There is pain and tenderness over the region of the abdomen. If the lesion is simply contusion, with partial laceration, the pain will be circumscribed. A limited inflammation follows, causing adhesion between the affected part and adjacent organs. Vomiting is usually present; bloody vomit indicates serious lesion of other viscera. The stomach may be inflated with hydrogen gas, or filtered air, through a stomach tube. If the walls of the stomach are intact, or but very slightly ruptured, it will be dilated, so that its contour can be made out by inspection and percussion. Complete rupture permits the gas to escape into the general abdominal cavity, causing no distention of the organ, and producing general tympanites. The following case¹⁷ will give a clearer conception of these cases:

N. W., age 32, died June 21, 1892. The patient was supposed to have fallen from a moving train, striking on his abdomen. On admission to the hospital he complained of great pain and tenderness over the abdomen, especially over the upper part, where the skin showed some contusion. No paralysis. Pupils negative. No vomiting. Catheter drew off 3 viij of clear urine. Abdominal tympanites, tender and tense walls. Pulse 100 degrees and feeble.

Next day after admission.—Restless; thready, rapid pulse; expulsive vomiting of greenish fluid; abdominal distention with dulness, except over the epigastrium; exploratory puncture disclosed reddish fluid.

Postmortem examination.—Weight of body 200 pounds. Greenish discoloration. Nourishment good. Weight of heart 5 oz., 11 dr. Pleural adhesions over posterior of both lungs. Lungs edematous. Peritoneum contained about two quarts of reddish, acrid, shreddy fluid, with penetrating, enduring odor. Peritoneal layers rough, and covered here and there with detachable membranes, beneath which were small hemorrhages. Fluid found especially around spleen and beneath liver. There was a small tear in the stomach. Stomach: There was a rupture in the walls of the stomach, near the lesser curvature, two inches from the pylorus; it extended for two inches in the serous coat and to a less extent in the muscular coat, and finally made a small opening in the mucous membrane (Fig. 3). Near the esophagus was a small area of contusion in the stomach, with no lesion of the peritoneal or mucous coat. On the mucous surface there was found a small round perforating ulcer, one cm. in diameter, situated exactly opposite the tear described above, and without any thickened margins, but with much shining mucous membrane, in a very softened state, surrounding the opening. No lesion in intestines.

Diagnosis.—Rupture of stomach; diffuse peritonitis; gastro-malacia, or round ulcer.

FIG. 3.—Traumatic rupture of the stomach. (Original from specimen in Rush Medical College Museum).

Owing to the fact that the stomach usually contains septic material, peritonitis would be expected to follow in all cases, though such does not seem to have been evident in Elliot's case, mentioned above. In the case just reported, gastro-malacia was an important factor in weakening the walls of the stomach. Shock is usually, if not invariably, attendant on such lesions.

Treatment.—In cases of simple contusion of the stomach, rest and external soothing applications will usually prove sufficient. No time is to be lost in treating complete rupture. The abdomen should be opened by an incision from the xiphoid cartilage to the umbilicus.¹⁸ By repeated inflation the visceral wound can be readily found. If extravasation has taken place, the peritoneum should be thoroughly flushed with sterilized water, and carefully mopped out with an aseptic sponge. After seeing that the stomach is entirely empty and hemorrhage arrested, close the rent by two rows of sutures—the first row is applied to the muscular and mucous coats, and is buried by the second, which includes the peritoneum

¹⁷ From postmortem records of Dr. Hektoen.

¹⁸ Amerleau Text-Book of Surgery.

and enough of the muscular coat to furnish a good hold. It is well to use drainage if the peritoneum has been contaminated. This operation requires all the precaution necessary to avoid shock—external heat, stimulants sub-cutaneously and per rectum. Strychnin hypodermically, and whisky or brandy diluted with warm water, can usually be relied on as stimulants. The patient should be nourished by rectal alimentation for at least four days.

The liver is frequently the seat of contusions, which may result in abscess; in some cases, as in fatty liver, it may cause embolism.

Rupture of the liver is usually accompanied by serious lesions of other organs. Wounds of the liver heal readily, and hemorrhage is usually arrested by approximation of the torn edges. In a lad who died four days after being struck in his right side by the shaft of a runaway cab, an extensive tear of the liver, four inches in length, was found, adherent by a blood clot. In this case death was due to acute peritonitis, the skin and bones being unbroken.¹⁹

Wharry reports a case which illustrates how injuries to the liver accompany those of other organs.²⁰ The patient fell from a window, striking on the right side of the head and shoulder, and bending the trunk suddenly and violently upon itself. At the autopsy, the liver, lung and kidney on the right side were found to be extensively lacerated, but there was no apparent injury of the thoracic or abdominal walls. The weight of the liver, in this unusual contortion of the body, was one of the important factors in causing the injury.

Treatment.—Where the patient's condition is such as to justify even slight hope of success, the abdomen should be opened and the wound closed. Dalton estimates that in three out of four cases recovery follows operation after stab wounds of the liver, if sponged and drained without irrigation. The same, or an even better estimate would hold good for rupture. Vanverts²¹ reported two cases of rupture, both of which were fatal; one in an hour and a half after injury, the other in twenty-four hours. He thought a prompt laparotomy might have saved the latter.

The spleen may suffer contusion from abdominal injuries, but other organs are involved. Traumatic rupture of the spleen results from direct violence, rarely from indirect. Falls, kicks and blows, fracture of the ribs, or a crushing force, as from the wheels of a vehicle, are the common causes. Fracture of the ribs was the commonest accompanying lesion in a number of cases studied. Among these cases was that of a child who had suffered a crushing injury, which had produced rupture of the spleen, total transverse rupture of the left kidney, rupture of the upper lobe of the left lung, with fractures of the seventh, eighth, tenth, eleventh and twelfth ribs: the broken ends of the seventh and eleventh ribs projected into the pleural and peritoneal cavities respectively. Emesis, convulsions and parturition are said to be rarer causative effects. Rupture of the spleen is usually fatal. If the patient is seen in time, an abdominal section should be made and hemorrhage stopped if possible. Excision of the spleen has been performed a number of times. Ashhurst²² refers to twenty-one successful cases of splenectomy for traumatic conditions. Lane²³ reports two cases in which splenectomy was performed for rupture; both cases

were fatal five hours after operation. Reigner²⁴ reports a successful case. Vulpius²⁵ maintains that this operation should be performed oftener. He has collected 117 cases of splenectomy, with a death rate of 50 per cent.; deducting thirty-two cases weakened by various pathologic conditions, the mortality of the remaining eighty-five cases is reduced to 33 per cent.

The pancreas, of all the abdominal organs, is the least liable to suffer traumatic injury. Rupture of the pancreas has resulted from severe contusing forces. Located in a very protected position, when injured, other important organs are complicated. If the pancreas should be crushed by a force not fatally injuring other organs or introducing septic material, the injury of itself need not prove fatal. Dr. Senn²⁶ has proven that subcutaneous crushing or comminution is, in itself, not a fatal or even dangerous injury, unless it interfere with the normal escape of pancreatic juice from the intact portion of the gland. Abdominal section will disclose the condition of the pancreas, and partial excision of the organ is justifiable in conditions seeming to demand it.

CONTUSED WOUNDS AND RUPTURES OF THE INTESTINES.

Postmortem examination has repeatedly demonstrated that blows, kicks, blunt and crushing forces may cause very serious injury to the intestines, without penetrating the abdominal wall. The force of a blow chiefly affects the distended intestines, and that portion directly contiguous to the point of impact.²⁷ While this may be the rule, there are exceptions, that while establishing the rule, are not self-explanatory. Why is it that some remote organ, carefully stowed away in seeming safety, behind a bulwark of other defending organs, is ruptured or destroyed by a force that leaves all the other organs unscathed? A rupture of the receptaculum chyli has been reported—all the other organs escaping serious injury.

Much damage can be done without external appearance of injury. Some years ago in the dissecting room of Harvard Medical School, a subject was found with the intestines torn in every direction and the spine extensively comminuted, yet there was no evidence of external injury. This subject, a man, had been caught between the dead-woods of two freight cars.

The nature of the traumatic force is an important element for consideration. The quick percussive or contusive blows, are not so frequently fatal as the crushing forces, though more common. A few cases of instant death have followed blows over the epigastrium. It is interesting to note the varied opinion of eminent authorities on this subject. Ashhurst²⁸ declared "that death may follow a severe blow over the abdomen." Bryant²⁹ says, "under certain circumstances, a trifling blow may give rise to alarming symptoms." Pirrie³⁰ considered blows over the stomach or duodenum more dangerous than over other parts of the abdomen. LeGros Clark³¹ said, "that if the doctrine be true that a blow over the abdomen may cause death, it must be a very rare accident."

The writer noted, after inflating the intestines of a cadaver, that partial distension of the intestines

seemed to increase their mobility, while extreme distention made them stand out firm and resistant. If a contusing force had been applied to the abdomen while its walls were intact, it is easy to understand how the resistant, distended intestine would be much more liable to be bruised or ruptured by the bony spine behind, than the more mobile, partially distended intestine, which would tend to slip aside. The empty intestine is in a collapsed condition, and has little power of escaping injury, when exposed to severe blows or crushing forces; however, it may slip to one side of the bony framework and escape injury. There are many chances for the intestine to escape injury in contusion of the abdomen, and it is important to be mindful of this fact, in considering the early performance of laparotomy for rupture of the intestine. The most common causes of death, after contusion of the abdomen, are hemorrhage and shock.³² Exploratory incision does not increase the danger, and should be performed. The danger is greatly increased by delay. Some cases of internal hemorrhage, otherwise fatal, can be saved by prompt action.

Dr. B. Farquhar Curtis, collected 116 cases of abdominal contusion, with the intention of studying their symptoms during the first six to twelve hours after injury. From the following facts, culled from his compilation, we can form our own judgment:

Causes in 87 cases reported:

	Cases.
Kick of horse or man	28
"Run-over" accident	13
Blow on abdomen by heavy weights	16
Blow on the abdomen by light weights	13
Fall upon projecting points	13
"Buffer accidents"	4

Nearly twice as many were caused by kicks as from any other cause. Evidently the great velocity and the small area of striking surface, are the elements that make a kick so dangerous. These same elements of causation enter into "falls upon projecting points." It is to be noted that "buffer accidents"—a term under which crushing injuries might be classified—are very rare, but four out of eighty-seven.

Location of the lesion, 113 cases reported:

	Cases.	Per Cent.
Injury to the duodenum	6	
Injury to the jejunum	44	
Injury to the ileum	38	
Injury to other parts of the small intestine	21	
Injury to the large intestine	4	
Injury to jejunum and ileum together	43	
Injury to first three feet of ileum	25	58
Injury to first one and one-half foot of jejunum	12	28
Injury to last one and one-half foot of jejunum	6	14

These facts support the theory that the danger of rupture is greatest in those parts of the intestine that are the most fixed in their position in the abdomen, but the large intestine must be excepted, on account of its more sheltered position.

The following variety of signs and symptoms were mentioned in these reports:

Shock may be delayed, as noted in three cases, but was present in ninety-five cases, or in 80 per cent.	
Consciousness at time of accident	54
Consciousness almost lost at time of accident	4
Consciousness lost at time of accident	11

Vomiting in seventy-two cases out of ninety in which it was mentioned. Urinary symptoms—condition noted in forty-seven cases.

Bloody urine	2	Cases.
Bladder function frequently disturbed:		
Retention	25	
Urination difficult	1	
Urination normal	17	
Tenesmus	4	
Pain in abdomen one of the first and most constant symptoms. Tenderness constant.		
Distention of the abdomen	42	Cases.
Distention of the abdomen absent in	16	
Tension of abdominal muscles.		
Tympanitic resonance.		
An area of dullness, on percussion, was discovered in six cases in the early stage and in two cases in the later stages.		
Loss of liver dullness.		
Among the later symptoms, temperature, constipation and fecal vomiting were almost constant.		
Duration of life—the average in 112 cases was forty-eight hours, after the accident.		

FIG. 4.—Traumatic rupture of the small intestine. (Original from specimen in Rush Medical College Museum.)

We can now sum up the symptoms from the foregoing facts. There is shock, with or without loss of consciousness; vomiting is usually present with the first symptoms, and constipation and fecal vomiting are almost constant later symptoms; there may be retention, or difficult urination, while pain and tenderness are constant symptoms. There will be various signs noted on physical examination—dullness, tympanitic resonance, discoloration, varying with the case and stage of progress; the pulse rapid, weak and irregular at times, temperature subnormal in shock, but rises during peritonitis, when this follows. Figure 4, an illustration of a traumatic rupture of the intestine, is an original drawing from a specimen in Rush Medical College Museum, taken from a man killed by a violent kick in the abdomen, this rupture being the only resulting lesion discoverable.

³² Curtis: Am. Jour. of Med. Sciences, October, 1897.

While, in our discussion some of the elements entering into the causation of subcutaneous wounds of the intestines have been considered, the condition of the tissues themselves has not been mentioned. Poorly nourished, diseased tissues will succumb most readily to any injurious force. Figure 5, drawn from a specimen in Rush Medical College Museum, illustrates this fact. The specimen consists of a portion of the pyloric end of the stomach and about two inches of the duodenum, taken from an old man who had received serious subcutaneous injuries, which ruptured a duodenal ulcer just below the pylorus and

FIG. 5.—Traumatic rupture of duodenum. (Original from specimen in Rush Medical College Museum). R, rupture in duodenum just below the pylorus; P, pylorus; S, folds of stomach.

fractured the second, third, fourth and fifth ribs, on the right side, and the fifth on the left side, besides causing some other very superficial contusions not of a particularly serious nature. Had it not been for the weakened condition of the intestine, due to this ulcer, the lesion would probably not have resulted from a force of no greater energy than the one received.

Treatment.—Patients who have received injuries to the abdomen, which can be satisfactorily diagnosed as simple contusion, should be kept in bed and on

an absolute diet for some days, when recovery, as a rule, follows.

If the symptoms point to rupture, laparotomy should be performed, as already suggested. The external incision should be made through the linea alba. First, check hemorrhage. The laceration may be readily found by using Dr. Senn's method, rectal insufflation with hydrogen gas or filtered air. Close up all lacerated wounds, being careful to secure apposition between healthy surfaces, and suture all rents in the mesentery. It is advised that an omental graft be placed over the contused areas surrounding lacerated wounds, so as to avoid subsequent perforation. Flush out the abdominal cavity thoroughly with sterilized water; insert ample drainage; then stimulate to overcome shock. Administer opiates to quiet the intestines and withhold food by the mouth for several days.

SUBCUTANEOUS INJURIES OF THE KIDNEYS.

The kidneys may suffer severe subcutaneous injury from external violence, such as blows and crushing-in the abdominal region; or internal strain, induced by unusual flexion or contortion of the body, as in Wharry's case before cited. Violent shock from falls may cause sudden compression from other organs, as the liver, and may produce contusion or rupture.

Symptomatology.—Simple contusion without laceration sometimes causes prostration and severe pain. There may be frequent and painful micturition, or suppression of urine. The face wears an anxious look. The pulse is rapid and there is fever. If the injury is severe, shock and collapse may follow. Hematuria is the important symptom in laceration and rupture; however, it must not be forgotten that hematuria may occur without any injury to the kidney. It may follow some injury of the abdominal wall, or the dislodgment of a thrombus. Sometimes it is due to transudation from the blood vessels. It may be due to tumor of the bladder, as in Newman's³³ case. Then again hematuria may be absent in rupture of the kidney. Maas reported seventy-one cases, six of which had no hematuria. Four cases in Keen's table³⁴ were without hematuria. Clots may form in the bladder, as in three of Maas' cases, and stricture or occlusion of the ureter may cause absence of external evidence of hemorrhage of the kidney.

Clot of the ureter may be dislodged and re-form, repetition of the process causing intermittent hematuria. Should it persist, hydro-nephrosis or atrophy results. In Butler's³⁵ case, a clot completely occluded the left ureter. There was total suppression of the urine for fourteen days. Death ensued, and at the postmortem, the *right kidney* was found cystic and atrophied to one-eighteenth its normal size. The *left kidney* was enlarged, showing evidence of old and recent inflammation; the ureter was distended with urine and blocked half way down with inspissated clots, which had entered the pelvis through a tear extending from one calyx far into the softened renal tissue. Both supra-renal bodies were decidedly atrophied, but no other signs of Addison's disease were present. As a rule, however, profuse hematuria follows injuries to the kidney, coming on at once or in a few hours, and lasting for days. It has been known not to appear until the eighth day.³⁶ Pain is usually the first symptom. It is most acute in the loin, but

³³ Quoted by Keen.

³⁴ *Annals of Surgery*, August, 1896.

³⁵ *Lancet*, Jan. 11, 1890.

ten inside the thigh toward the knee, the testicle being retracted. The lumbar region and abdomen, on the side of the affected parts, are very tender, though no bruise may be visible. Passage of clots through the ureter gives acute paroxysms of pain, with nausea and vomiting. Pain is not a constant symptom, as shown by D'Arcy Power's case,³⁷ in which there was absence of pain with hematuria for two days. Hemorrhage may take place into the surrounding tissues or beneath the capsule. It is, as a rule, apparent early, and is recognized by the ordinary signs and symptoms of internal hemorrhage. There will be an external increasing area of dulness and swelling in the lumbar, and, it may be, in the iliac regions. Swelling and dulness in intra-renal distention is circumscribed, more slowly formed, and later. If confined to the pelvis and ureter, the tumor will rarely be appreciable, unless it burrows under an easily separable capsule. If it ruptures into the peritoneal cavity, a fatal result is probable, especially if a large vessel be ruptured, for there will be no pressure to resist blood extravasation. Secondary hemorrhage may occur. Royer³⁸ observed hematoma six weeks after injury.

Mortality and Treatment.³⁹—Keen's tables give 118 cases of rupture of the kidney. Of this number one was under treatment when reported. Of the 117 cases, sixty-seven recovered and fifty died—a mortality of 42.7 per cent. From these cases the following seventeen deaths, in which treatment was futile or impossible, should be deducted:

The other kidney absent	1
Both kidneys injured	2
Found dead	2
Died of other injuries in addition to renal injuries	12
Total	17

Of the 100 remaining, sixty-seven recovered and thirty-three died—a mortality of 33 per cent. Early death, without nephrectomy, occurred in thirteen cases, eleven dying from shock and hemorrhage, and two from peritonitis in addition. There were ten late deaths without nephrectomy, all excepting two due to sepsis, one due to continuous, the other to secondary hemorrhage. Dr. Keen says, "had nephrectomy been done in the twenty-three cases, it is, I think, a fair presumption that ten of them would have recovered, which would reduce the mortality to 23 per cent." There were twenty-two of nephrectomy with eight deaths—a mortality of 36.4 per cent.; there were forty-two deaths in ninety-five cases without nephrectomy—a mortality of 44.2 per cent. This makes a difference of 8 per cent. in favor of nephrectomy, though the operation was only done in the most serious cases, which makes the value of this life-saving operation more evident, when we recall that the large number of cases without operative interference, were the lighter cases of injury. It becomes evident from consideration of these facts, that operative measures could have saved many of the ninety-five unoperated cases. A study of this same table shows secondary nephrectomy to be nearly twice as fatal as primary—8.5 per cent. to 20 per cent.

Lumbar nephrectomy is the preferable operation, because it is less apt to cause infection of the peritoneal cavity. In cases pointing to intra-peritoneal

hemorrhage, or to serious injury to other abdominal viscera, abdominal section should be made. Hence a very careful study of all the conditions in each case is absolutely necessary to the best success.

Fifty of the 118 cases in Keen's tables died. The causes of death were tabulated as follows:

Primary hemorrhage and shock	11
Continuous hemorrhage	1
Secondary hemorrhage	2
Injuries to other organs	12
Found dead	2
Absence of the other kidney	1
Peritonitis	5
Coma	2
Pneumonia and empyema	1
Suppuration and exhaustion	10
Anuria	1
Nephritis	1
Uncertain	1
Total	50

It is to be noted that primary hemorrhage and shock (eleven), continued hemorrhage (one), and secondary hemorrhage (two), caused fourteen deaths; and suppuration (ten), empyema (one), and peritonitis (five) caused sixteen deaths; this certainly proves that hemorrhage and sepsis are the two great causal factors of fatal kidney rupture. Since the majority of recoveries in rupture of the kidney are the less severe cases, and since the graver ones do not recover, unless by operative interference, it is clear that the duty of the physician or surgeon is to resort to exploratory incision. It adds but little risk and will save a greater proportion of lives.

Rupture of the ureters may be produced by the same or similar causes inducing injury of the kidney. Barker⁴⁰ and Godlee,⁴¹ have reported a case each, in which nephrectomy was performed, and recovery followed.

SUBCUTANEOUS INJURY OF THE BLADDER.

A solution of continuity in the walls of the bladder may be caused, by violent concussion, or by displaced fragments of bone in fractures of the pelvis. Owing to the fact, that the organ is well protected by the pelvic bones, and is usually in a state of only partial distention, such injuries are rare.

Rupture of the bladder may follow violent concussion, especially if the organ be distended and the force be exerted on the lower abdominal region. This force may be from a kick, a blow or crushing pressure. The accident is more frequent in men than women, in whom parturition and continuous pressure by uterine or ovarian tumors, are causative factors. Some years ago, Prof. Hektoen reported a case, that is a good example of the effect of resistant pressure from tumors. A woman died after being kicked in the abdomen, and beaten by her brutal husband. The post-mortem examination showed a tear one and one-half inches long in the posterior wall of the urinary bladder, near the fundus. This tear was transverse, ragged, and free from signs of inflammation, as was also the peritoneum. In the uterus were three sub-serous fibro-myomata, which filled the pelvis and acted as a firm, resisting body, against which the bladder was pressed when injured.

We can gain some idea of the frequency of the injury from the fact that in 8,000 surgical cases in the Cook County Hospital, between 1889 and 1892, five were proven to be traumatic rupture of the blad-

⁴¹ Trans. Clin. Soc., xx, 219, quoted by Keen.

der.⁴² The St. Bartholomew Hospital reported but two cases of injury to the bladder, out of a total of 16,711 surgical cases from 1869 to 1875.⁴²

Symptomatology.—The symptoms may be obscure. Two out of seven cases reported by Dr. Herrick were not diagnosed until after death. The rupture may be intra- or extra-peritoneal. Fortunately, it is usually the latter. When extra-peritoneal, the signs of infiltration into the pre-vesical connective tissue or into the vesico-rectal or vesico-uterine space, are readily recognized. External palpation or the introduction of the finger into the rectum, will reveal a peculiar doughy condition of the tissues. The hypodermic needle may withdraw a few drops of bloody urine from the tissue. In case of intraperitoneal rupture, shock is more marked, and there is dulness in the hypogastric and inguinal regions. The passage of a catheter or sound may confirm a diagnosis. Should the sound be felt beneath the abdominal wall, rupture is demonstrated. The passage of a small amount of bloody urine, with or without the catheter, is a suspicious sign. If the urine is passed more readily by aid of the abdominal muscles and pressure on the abdominal wall, evidence of a more convincing nature is added, but is not conclusive.

Eight or ten ounces of liquid will distend the bladder, so that it will rise into the abdominal region; hence, inject at least this quantity of some aseptic fluid, as sterile water, into the bladder. In case but a part of the water is returned, and the viscus does not rise, the organ is ruptured. Filtered air, or hydrogen gas may be injected, and in case of a rupture into the peritoneum, it will escape into the general peritoneal cavity; or form emphysema of the cellular tissue, in case of extraperitoneal rupture. Peritonitis does not necessarily follow intraperitoneal rupture, because urine has been demonstrated to be aseptic. The case of Dr. Hektoen referred to above did not contract peritonitis, though living nine days after the rupture, and with her abdominal organs bathed in urine.

The symptoms are masked by drunkenness, pain and shock being but slight. That drunkenness is an important etiologic factor, is well known. "It furnishes the abundant secretion of urine; a paretic, and consequently distended bladder, which rises above the pelvic brim where it is exposed to injury; and a relaxed abdominal wall, so that the force strikes with unchecked vigor upon the viscus with the walls tightly stretched."⁴³

Figure 6 represents a bladder with a very extensive rupture in its posterior wall, which readily allowed a passage into the peritoneal cavity. The patient passed his urine by aid of the abdominal muscles, pressing the urine through this very large rent. This caused a diagnosis against rupture by a consultant.

Peritonitis did not occur until after catheterization by some five different persons. The infection was undoubtedly due to the use of a septic catheter.

The patient in this case was drunk at the time of injury, and the symptoms were so masked that the physician originally called in thought it merely a pain in the abdomen and of no serious nature. The temperature never rose higher than 100 F., and the pulse was about 120. A gradual failure of strength took place and the patient died fifty-two hours after admission to Dr. C. W. Earle's hospital, and four days after being seen by the first physician. This case

was reported by Dr. Jas. B. Herrick, who called particular attention to the fact that "when the rent is large and especially when there is no peritonitis, bloody urine may be obtained in quantity and in a stream."

We are inclined to the belief that operative interference when free from sepsis, would save all such cases or at least a large percentage.

Treatment.—In extraperitoneal rupture, immediate and free incision into the infiltrated regions, should be made. In order to find the rent in the organ, an incision should be made, as in suprapubic lithotomy. The rent should be found and carefully sewed up by Lembert's sutures. Fine silk is the best material, and should be inserted through the peritoneal and

FIG. 6.—Rupture of the posterior wall of the bladder. (Original from specimen in Rush Medical College Museum).

muscular coat, but not the mucous coat. It is well to test the sutures by distending the bladder before closing the abdominal incision. Intraperitoneal rupture demands a longer abdominal incision. The peritoneum must be thoroughly flushed out with aseptic water, or bichlorid solution (1-2000). In case of peritonitis, a drainage tube should be inserted. When it is recalled that intraperitoneal rupture is almost invariably fatal without operative intervention, the physician's duty is plainly indicated—operative interference is imperative.

INJURIES OF THE PENIS AND URETHRA.

It is seldom that wounds of the penis are met with. Fracture of penis has been known to occur, when the organ was in a state of extreme erection. Laceration

⁴² Herrick: The Medical News, Feb. 25, 1893.

⁴³ Herrick: The Medical News, Feb. 25, 1893.

of the organ sometimes occurs. The treatment for such injuries is the same as for other parts similarly affected.

Rupture of the pendulous portion of the urethra is rare. While it is difficult to treat, it is not dangerous as a rule. The symptoms are what one would expect, pain, hemorrhage and swelling. Evaporating lotions, rest and very gentle catheterization is all that will usually be required for satisfactory results. Rupture of the urethra may be due to instrumental violence. Most cases reported have been caused by falling astride of resistant bodies. The writer had occasion some years ago, to assist in caring for a young man who had fallen astride a timber, literally crushing the bulbous portion of his urethra. In these injuries, the pubic bones and the vulnerating bodies furnish the two hard, unyielding factors, between which the soft urethra is contused, lacerated or crushed. There have been a number of explanations for the mechanism of urethral rupture, but the one just mentioned is sufficient for all practical purposes.

Treatment.—In mild cases, periodic use of the soft catheter, well greased with carbolized oil, may be sufficient, provided the patient is kept at rest. Fever and local swelling call for decided steps. Should extravasation be marked, and it be possible to pass a full-sized catheter, the instrument should be allowed to remain. The tissues involved in the extravasation should be laid open. It may be impossible in some cases to find the proximal end of the torn urethra, even after perineal section. Such was the condition in the case mentioned above; suprapubic cystotomy was performed, and retrograde catheterization soon located the proximal end. An elastic catheter was allowed to remain and the perineal wound was sutured. In the course of three or four weeks, the patient was discharged, after having been instructed in the art of passing the sound on himself, to avoid the cicatricial tissues closing the urethra by contraction. Where possible, it seems wisest to suture the divided ends of the urethra with catgut. Do not include the mucous membrane in the sutures.

[NOTE—Owing to limited time it has been impossible to treat this subject as fully as the writer desired. For this reason he did not deem it advisable to undertake the discussion of subcutaneous injuries to the brain. Only traumatic injuries of subcutaneous soft parts have been considered in this essay. The writer wishes to acknowledge his indebtedness to the various sources from which the information in the foregoing pages has been obtained. It has been his intention to mention by proper references, the authorities to whom credit is due. He is especially grateful to Prof. L. Hektoen for the use of his postmortem records, from which much very valuable information was acquired; also for the use of specimens from the Rush Medical College Museum, which enables the presentation of four original illustrations in this production.]

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

(Continued from p. 92.)

XX.—GUNSHOT WOUNDS, AMPUTATION, EXARTICULATION,
RESECTION.

Gunshot wounds in general; Gunshot fractures; Conservative surgery; Gunshot wounds of the joints; Injuries by cannon balls; Primary or secondary amputation; Method of amputation; Exarticulation; Resections.

The twentieth chapter of our historical work! Has

not the patience of the reader been already exhausted? Has not my work been already laid aside, with a "never more"? I would give something to know as to this. Yet to every colleague who has remained true to me until now I will extend a grateful hand and seek to refresh his severely tried patience, at the close, by a theme of more general interest, *gunshot wounds*.

To what teachings did they pay allegiance, in the year 1750, in case of a simple gunshot wound? Even then had begun, as previously mentioned, an opposition to the excessive probing of gunshot wounds. They distinguished a primitive and consecutive hemorrhage, which, if the scab dropped off, appeared more frequently at night than during the day. The bullets (of lead, iron and copper) were extracted as soon as they could be distinctly felt; a number of instruments were invented for that purpose, and the patient was placed in the same position as that in which he had received the wound. This principle originated with A. Paré. It was the general rule to enlarge the openings of every gunshot wound as soon as possible. Formerly this was done more frequently in a bloodless way, by means of absorbent lint and dilation, later with the knife. They also began to stuff up the path of the bullet with lint and to close it with the seton. The bandage materials were mostly irritating in order to accomplish a quick shedding of the scab and an abundant granulation.

It was characteristic of the advancement in the teachings on gunshot wounds, that it took place in a purely empiric way. There was no mention of principles based upon a physiologic foundation. How the healing process in the path of the bullet took place, no one knew; how the size of the wound was proportionate to the velocity of the bullet, no one considered. These and similar questions were first raised by John Hunter. He accordingly looked upon the accomplishments of the French military surgeons with insignificance, and said that "among the French the art of destruction is very highly perfected, while that of healing has not reached a like perfection. . . . There has been little written on gunshot wounds and what has been written is so superficial that it deserves no special attention. Simple practice without principles appears to have been the guide of those who have occupied themselves with this branch of surgery. And if one fixes his eyes upon the practice hitherto followed, he finds it extremely limited and almost reduced to the ordinary rules of surgery." Hennen later sought to detract from these complaints when he extolled to the highest point the French surgeons before Hunter's time. We will submit a few of Hunter's theoretic doctrines on detailed questions. He distinguished gunshot wounds from other wounds, especially when fresh; then they demanded a particular kind of treatment. This classification depended chiefly upon the velocity of the bullet. If this was slight it occasioned only a small injury, seldom a fracture. If the velocity of the bullet was sufficient to fracture the bones the shattering was much more extensive than in the case of greater velocity; in the latter case the bullet carried away a piece of the bone almost as if by pincers. So gunshot wounds sometimes simulated a knife wound. The denser the bullet the less matter was rubbed off from it, and this was more abundant at the entering point than at the exit (Le Dran had taught the distinction between the two). The reddening of the skin in the canal of a superficial shot

wound was, according to Hunter, by no means of an inflammatory nature. He said it was like the rosiness of the cheeks; that the small blood-vessels allowed the red part of the blood to flow through more readily than usual. Healing could only take place by way of suppuration, although when there was very little contusion at the point of exit a *prima intentio* was possible. As a rule, Hunter observed the beginning of the healing at the point of exit, sometimes the contrary; it appeared to him to be the rule that the lower end of the bullet canal healed more quickly than the other.

In general they believed in the existence of the so-called air grazing shots, and attributed the most dangerous injuries from the simple grazing of the bullet to the pressure of the air. Tissot estimated the force of this and Plenk ascribed it to the electricity generated in the bullet by the explosion. The first who contradicted the air grazing shot was le Vacher of Bisançon (1768); he traced the injuries to an actual contact of the bullet with the body and declared them to be simple grazing shots. Richter agreed with him.

The after-ills in severe shot wounds were in general known; the pyemic fevers can be easily studied from the writings of Bilguer and Larrey. It is striking that Hunter, who was acquainted with phlebitis and expressed the supposition that its fatal results depended on the entrance of the pus into the circulation, said nothing of pyemia.

Among the practical questions, the *enlargement of the path of the shot* was earnestly discussed by surgeons. They adduced as advantages that it facilitated the extraction of foreign bodies, created a better outflow for the extravasation, transformed crooked wounds into straight ones, etc. The incision should be made immediately in order to promote the expansion, and should extend throughout the whole path of the bullet to the bottom of the wound, and in fractures should reach the bones and indeed extend over the whole length of these. Being earnestly recommended by A. Paré and Wiseman, they found acceptance everywhere and in France, as well as in Germany, were sadly abused. They were, indeed, legally prescribed in the Austrian regulations for field-surgeons (1788). Even at the end of the century they were recommended by J. Bell, and especially by Percy, who sought the first indications of healing in the transformation, so far as possible, of shot wounds into knife wounds. One of the first who opposed this nuisance was Ravaton. He allowed enlargement only in order to promote the discharge of pus, but never if there was danger of cutting through large blood-vessels and nerves. That he considered it necessary to describe the incision on every separate part of the body shows the low grade of anatomic culture among his countrymen. Theden had, after increased experience, abandoned the common use of the incision. J. Hunter especially deserves credit for having confined the incisions to narrower limits. Yet it must be recognized that Jackson of Dublin had, a few years before him, energetically opposed the principle of enlargement (*London Med. Jour.*, xi, 1790). He observed that it increased inflammation, delayed the healing, and caused danger of joint affections in consequence of the admission of air. Desault and the other surgeons in the Hôtel Dieu (1792) had long before desisted from cutting into gunshot wounds when Hunter had entirely discarded the method as

an ordinary practice (1794). It contradicted the precept which held good in all other wounds, that as such they should not be enlarged. The practice in gunshot wounds should be also that of civil surgery. Without promoting the expansion the incisions increased the inflammation, readily closed again, and delayed the healing. Hunter considered dilation as required only under certain definite indications: 1. If foreign bodies irritated or pressed against an important part. 2. If a ligature was demanded for stopping hemorrhage. 3. If in a head wound a fracture was presumable. 4 and 5. If bone splinters and foreign bodies could be immediately extracted with advantage and their retention would have evil consequences. 6. If viscera protruded from the wound (bowel). 7. If important organs are compressed, as the lungs in case of rib fractures. On the other hand, Hunter limited the indications too narrowly; for when the bullet lay at some distance from the sound membrane and could be felt, then one should wait until the entering point had become inflamed. As a reason for this principle he alleged that the wound could readily heal with the bullet inside, that the inflammation occurred, therefore, not from the injury, but from the contact of the part with the external air and hence the admission of air must be prevented. In respect to the extraction of the bullet, he counted too much upon the help of nature and argued that the direction of the bullet was quite uncertain, for the heavier it was the easier would it curve and run obliquely when resisted. B. Bell and Boy also condemned the abuse of dilation. The latter criticized the extraction of a foreign body when the operation had more unfavorable results than the presence of the bullet. If it was necessary, the earlier it was done the better.

The number of *instruments for the extraction of bullets* had become very large; Ravaton alone had invented three. The apparatus grew simpler with time. Hunter came to think the usual ball extractor almost inapplicable. Many would banish all the hooks, screws, bores and ball extractors, and extract the bullet with the finger, or if that failed with a pair of small pincers (Richter). Finally they used almost entirely small bullet-tweezers, spoons and bores (Percy). The movement of balls healed in the bones was known; Ravaton observed a bullet situated in the antr. Highm. for twenty-five years, after which time it came out through the palate. Le Dran noticed one a year in the sella turcica, Pallas one for fifteen years in the os ethmoidale.

The *bandage material* also gradually became simpler, both in respect to number and to composition. The one bound fresh gunshot wounds with irritants (alcohol, wine and salt-water) in order to restore the weakened vital force of the vessels and to hasten the separation of dead from living matter. Another applied emollient, sedative remedies (tepid water and digestive salves), which were said to support the free discharge of secretions but to allay swelling and inflammation. As a rule the whole wound was filled loosely with lint that it might absorb the pus and protect the muscles from sharp splinters of bone. Dry lint was used by Ravaton, and over it a diachylon plaster and a large compress wet with alcohol. On the third day he had the bandage removed, the channel of the shot syringed with oil, ungt. basilicum laid in the wound and over that a pledget with the same salve, and a compress dipped in vulnerary water applied. The bandage must not exert the slightest

pressure, and was removed twice a day. Theden's arquebusade-water made something of a sensation: "Take sorrel water and alcohol, one and one-half pounds of each, half a pound of white sugar and five ounces of spirits of vitriol; mix these and digest the mixture for eight days, then filter it." Theden preferred this arquebusade to all other remedies, not only for gunshot wounds but also for contusions, burns and swelling in fractures, luxations, etc. Surgeons were not united as to the use of warm and cold applications. Theden changed his opinions in so far that he had at first regarded warm poultices as entirely necessary, but in later years often found warmth injurious and observed the best results from cold applications. Jackson's experience was similar. On the contrary Hunter considered the cataplasma the best bandage for gunshot wounds and most lacerated wounds. B. Bell took the middle course, in that he used poultices only in the beginning but removed them as soon as suppuration ensued, because they relaxed the wound and increased suppuration unnecessarily. The Frenchman Boy, who a year later than Hunter, and entirely in the spirit of this great surgeon, wrote an excellent work without mentioning him, recommended common water, at first tepid but gradually cooler. "All salves and the damnable irritants are of no avail. . . . Let us simplify whatever can be simplified." He protested against the general use of poultices, and used them only to induce suppuration. Until the appearance of suppuration he rarely bandaged, and then kept the bandage wet. The injured limb was laid so that the muscles were relaxed as much as possible, and a bandage adjusted from the under part of the limb across the wound and above it in order to diminish the involuntary muscular movement and the pain; he laid the greatest stress in general upon the methodic adjustment of the bandage. He decried the drawing of a seton through fresh gunshot wounds (Bell), and availed himself of this instrument only in case the pus could not flow freely. Boy sought to restore to its rightful position the use of the syringe, against which a prejudice prevailed, but he cautioned against too strong injections on account of the possible laceration of the cellular tissue. After Mursinna had called attention (1796) to the fact that in many injuries the simplest treatment is the best, that gunshot wounds with injuries of the bones healed more easily and quickly if they were not cut or stopped up, but were only covered with a common wound salve, a great simplification in the treatment of wounds and the technique of bandaging began in the first part of our century with V. von Kern of Vienna (1810). With the exception of lukewarm water, which he recommended as the only covering for a suppurating wound, he considered that there is "no other salve nor balsam to further healing but the balsam which nature herself offers and which no apothecary can give us; the wound itself provides it. Accordingly everything which is used externally with this object is thoroughly injurious." With inspiration Kern said in a pamphlet to the surgeons in the Napoleonic wars, "let us also lay aside all salves and balsams; let us once forget the cinchona decoctions and all other expensive external remedies which have been hitherto employed. Let us give up the use of lint and all the bandages prepared from it, namely, the setons, pledgets and the like; they are foreign bodies, they can only irritate. Let us abolish the bad custom of filling wounds with lint; for it hinders the complete discharge of matter

produced by the pus and induces putrefaction of the wound. Let us desist from the use of artificial bandages: it is only expensive, for it wastes so much linen which might be turned to other uses! Let us avoid all those liquid balsams which are injected into the channels of gunshot wounds; let us discontinue the rigid pressure with the hand along the course of these channels in order to force matter out through them. It only irritates the injured part and maintains a continual condition of inflammation! . . . Follow my example. By the use of these principles you will save the soldiers endless pain and millions to the State."

In the general treatment *blood-letting* stood foremost. At first wantonly abused, they later began to limit it. It was always evident that the soldiers, exhausted by poor food and fatigue, bore repeated bleeding badly (Lombard), and that the strength must be preserved for the excessive suppuration. Therefore Hunter permitted only a moderate letting of blood, and Boy discarded it altogether as a general remedy. More and more the debilitating treatment was replaced by an invigorating one. Peruvian bark came into use, especially in England, in inflammations following injuries and operations (Hunter), and also in suppuration and gangrene.

They sought to arrest *hemorrhages* (see Chap. 14) from gunshot wounds when only a branch of an artery was injured, by direct ligature, or if that failed, by styptics and compression. But if a large artery bled they amputated (Ravaton). Bilguer had already conceived the idea of binding the main stem of the femoralis and the axillaris, in the hope that the small side branches would enlarge; even in case of shattered bones with arterial hemorrhage he advised ligature or compression and opposed amputation. Then Theden sought to displace the ligature with the tampon. Boy declared compression entirely unreliable, always used a stricture and only in the rarest cases considered the application of a ligature necessary. Since Larrey the laceration of the main artery was no longer regarded as an indication for amputation.

In case of *gunshot fractures* they amputated with a readiness scarcely to be believed, until in the middle of the century. In order to explain this we must anticipate the history of amputation. In Heister's time the rule was to amputate every limb with a shattered bone or an injured joint; the possibility of preserving it was considered as exceptional. J. L. Petit had advanced this doctrine. The causes of this mania for amputation reach far backward. In the fifteenth and the first of the sixteenth centuries the operation was always unusual but crude. The better surgeons sought with great patience to heal the most dangerous injuries and regarded amputation as the last resort (F. Würtz and Paré). Then came the age of Louis XIV. with its crowds of ignorant barbers. But the war developed a few skilled surgeons who, through large and bold undertakings, quickly became celebrated. But instead of improving the miserable methods in the treatment of gunshot fractures, they went over to the operation. Ever since Paré had applied the ligature after amputations and Morel had invented the tourniquet, the great fear of hemorrhage had vanished; surgeons had become more courageous. It was thought that the rarity of operations was to blame for many deaths, while the enormous mortality in the hospitals was due only to the bad treatment of the fractures. The men who fell into this error set the fashion for all Europe; in a

short time amputation became the most common operation. For example, Schmucker saw, in the year 1738, in the Hôtel Dieu in Paris, a double amputation of both thighs made on account of a simple fracture. The French surgeons in the Prussian army, who came from this school, cut off arms and legs without discrimination. A reaction began. Le Dran, indeed, and Bagieu were already convinced that amputations were conducted without due consideration; but the Frenchman Boucher first opposed the abuse in gunshot fractures, especially. He showed (*Mém. de l'acad. de chir.* ii, p. 304) that two-thirds of those so operated upon almost always died, while of 165 fractures which were treated without amputation not one resulted fatally. When the Académie de chirurgie (1754) offered a prize question on the necessity of amputations and the time for them, Faure won the prize with the answer that one should amputate in gunshot fractures in the second period.

During these discussions Bilguer appeared (1761). He boldly resisted the generally prevailing views and threw the gauntlet to all surgeons. He made it a rule to treat all gunshot fractures and joint injuries conservatively and to regard amputation as an exception. *Our conservative surgery began with Bilguer.* He protested against most of the indications for amputation and admitted only such a laceration of a main artery that the nourishment of the limb seemed impossible and extensive inflammation. Bilguer treated gunshot fractures in the following way: The wound was boldly enlarged by an incision which reached the bone and extended the length of the muscle. Loose splinters and foreign bodies were immediately extracted, firmly fastened fragments were brought to their proper position with the finger and left to nature, which sometimes healed them. Sharp, protruding ends were sawed off with a small saw, "for which one must have various thin, narrow, curved and straight blades." "In this way we have, with the greatest success, sawed pieces of bone three or four inches and more, from the bones of the lower leg, forearm and upper arm." Bones of the head and foot should be obstructed, be separated and taken out. A bullet fastened in the cavity of a bone was removed with the trepan. The wound was filled with lint from both openings of the channel, pledgets, compresses and a circular bandage laid around it and these were wet, for three or four days, with spiritus vini. Later he recommended digestive salve and emollients. The limb was lain in extension between board, pastebord or straw splints. Bilguer openly admitted that this conservative method caused the patient much pain and the surgeon much trouble and that it would bring about a cure only in the hands of skilled and experienced surgeons. If one asks for the results which he reported, the following figures give the answer: During the Seven Years' War he attended 6,618 wounded in his hospital, from its establishment to its suspension. Of these, 5,557 men were again fit for active service, 195 were half invalids, *i. e.*, fit for the garrison and civil service, 213 complete invalids, among whom not a single amputation had been made, and 653 died. Those 408 invalids all had "severe fractures, that is, shattered and bruised injuries to the bones . . . for at least everyone among us knows very well that none of our soldiers could become invalids on account of head and flesh wounds." He added that "it might be said

that perhaps among those who died from their shattered limbs, some might have been saved if their limbs had been amputated at the right time and in the proper manner," but I also for my part can assert, that of the very many who during the first years of this war lost the limbs on account of severe wounds scarcely one or two have survived." And amputation in the field seemed to him very rarely indicated because it was impossible to perform it on the battle-field and a secondary amputation should be forbidden for many reasons. "Throughout the whole Seven Years' War I have had no one under my supervision lose a limb by amputation, and I can bring forward 1,800 cases in which I have saved the wounded from this most horrible operation." Caries, which might develop after gunshot fractures, did not appear to him an indication for amputation. "For caries we have found it necessary to do nothing more than expose the bones more or less according to the nature of the difficulty, then to scrape them with a knife or perforate them with a small bore or a sharp brad, or, if the caries extended to the other surface of the bone, to bore with a tampon in more than one place, or even, as in case of the hands and feet, to remove whole carious bones, or in large bones entire carious parts, with the help of this or that instrument and of the hand." In order to confirm his conservative principles by facts Bilguer mentions, in his work on amputations (1761), fifty-one cases of serious injuries to the bones, which had been treated in the field hospital at Torgau with the best success, by him and by other surgeons of the army. After the close of the war, in his surgical observations (1763), he was able to add 118 likewise conservatively treated cases "of shattered limbs and joint injuries." He discussed only severe injuries (extensive destruction of the diaphysis or the joints of hollow bones, which frequently were occasioned by canister shot or cannon balls). Among these 169 cases, 9 fractures of the thigh were healed, 42 of the lower leg, 19 of the ankle, 11 of the foot, one of the shoulder joint, 9 of the head of the humerus (among them one in which the humerus was exarticulated almost entirely from the shoulder joint by a blow), 16 of the diaphysis of the upper arm, 22 of the elbow joint, 9 of the forearm, 3 of the wrist, 8 of the hand (among them 5 in which the hand was shot or cut half off), and 6 fractures of various bones of the extremities.

Bilguer's service was extraordinarily great for that time of mania for amputation. But his mistake was in the extravagance that would displace amputation almost altogether. Although a hundred years have passed we have not the right to cast a stone at him on that account. Though conservative surgery has made so great progress since the time when, sometimes practiced with foolhardiness, it cost so many lives, we are not yet through. It is to Bilguer's discredit that he published cures almost entirely and no fatalities, and that he noticed many observations of entirely unknown surgeons, upon which one could not rely. Certain of his contemporaries might assert that no surgeon merited so much from the human race as he, and shortly afterward Ravaton also might have come forward with conservative cures of complicated gunshot fractures (*l. c.* 2. Ausgabe 1768; this is lacking in the first edition); they raged against Bilguer from all sides. Among Frenchmen, Martinière charged against him that the many incisions caused more pain than amputation, which led to a quicker and more certain healing, and finally that a stiff and useless leg

was the price of that useless treatment extending over months. And Morand thought this treatment "so cruel that one is dismayed even to read of it," and the number of external remedies so great that one is reminded of the charlatan, and that Bilguer's prescription's were faulty and too expensive. For example, a warm poultice applied in case of gangrene, cost 2 livres 10 sous. "Much is German balderdash . . . much is written obscurely without intelligence and without tact . . . is madness a proper term to use of French surgeons who have the greatest reputation of any in the world?" An opposition was also raised in England. According to Charles White and Pott there were always some cases in which amputation was unavoidable, and Pott regarded the vaunting of remedies by which amputation was rendered unnecessary as quackery. In case of shattered bones he amputated immediately before inflammation had set in; for if this had already arisen, or if the air had already penetrated with injurious effect, then the operation only hastened death. The question as to whether more men with complicated fractures died without amputation than after the operation, according to his opinion, a single surgeon could never answer; but according to all experience the danger to life is greater if one seeks to save the limb. The objections of Pott and Morand, with whom Van Gescher allied himself in an exhaustive criticism, were intellectual and were written with great insight, inasmuch that they contributed much to support the doctrines of the German surgeons in their development. The attacks upon Bilguer from abroad had no end until he found a warm friend in the Englishman, Kirkland. The latter loudly proclaimed the principle that far more skill and art were required to save a limb than to cut it off, for there doubtless are cases when operation is unavoidable. "One must obviously seek to save the limb when there is even a slight probability that it can be saved;" however, the only consideration should not be as to whether there is less danger with amputation than without it. What man would gladly incur some danger in order to save a limb, . . . it is incredible what nature can do." Kirkland did not consider amputation absolutely indicated either in fractures of the joints, wounds of the large blood vessels or in caries. With certain limitations B. Bell agreed with Bilguer and would not amputate in case of fractures with slight injury to the soft parts, but would operate immediately in severe breaks with splinters, especially if they pressed into the joint. In doubtful cases he advised conservative treatment, since if that failed there was always time for an operation, and the secondary often gave better results than the primary. Frequently external conditions decided it. For example, Bell made it a rule to amputate after battles all complicated gunshot fractures immediately. To be sure a few limbs were lost in that way, but certainly far more human lives were saved, which without amputation would have been lost. If we look about us at Bilguer's countrymen we observe Schmucker take the golden middle course. He charged against some French surgeons that they often amputated unnecessarily; but there were always cases when amputation could not be avoided without exposing the patient to mortal danger. "It is just as extravagant to wish to abolish amputations altogether as to cut off all limbs without distinction. . . . Whether it is a blessing to live after amputation is a matter concerning which the surgeon does not have

to discriminate; his duty is to preserve life as long as possible." Richter, who advised immediate amputation in case of severe splintering of the joints and laceration of the larger blood vessels and nerves, considered it impossible to give any general rule for the rest, since each individual case must be specially judged.

It was sought to cure gunshot fractures of the diaphysis of the *upper arm* in metal splints with the elbow joint bent, while fractures of the *caput humeri* and of the lower condyles for the most part demanded amputation (Ravaton). Attempts were made to cure considerable injuries by the conservative course. Once a humerus was shattered two inches below the shoulder joint, and the bones, muscles and cuticle so lacerated that the forearm hung from the upper arm by only a mass of muscles an inch and a half thick, which, by good fortune contained the large vessels and nerves. A cure was accomplished after three months with two splints (Seeliger). Gunshot fractures of the *forearm* had a better prognosis than that of the upper arm; there was no longer any talk of amputation.

The great danger in gunshot fractures of the *thigh* was sufficiently recognized. Ravaton indeed observed imperfect cures, but death always ensued if the bone was broken in its entire thickness. Then in spite of great care no remedy availed; neither incision, extraction of the splinters, nor the most careful bandaging in a metal case with apertures, in an elevated position. Ravaton therefore advised amputation and suggested a method of exarticulation. On the contrary he cured fractures of the trochanter after extraction of the ball if it was lodged in one of the condyles. Isolated cures of gunshot fractures of the diaphysis were indeed known to J. L. Petit who, however, preferred amputation for the sake of safety, also to Bilguer and Desault and to J. Hunter who saw such a one proceed successfully, as a simple fracture. Nevertheless, amputation was in general agreed upon. Schmucker regarded fractures close above the knee as less dangerous on account of the few musculatures, and considered an operation not urgently indicated, but amputated immediately in case the bone was broken in the middle or higher up. Boy's opinion was clear and decided. Convinced of the extraordinarily difficult treatment of all fractures of the thigh whose fragments it was almost impossible to fix, impressed by the especially great danger in splintered fractures, particularly in the upper third of the bone, he said: "Amputation is necessary in most femur fractures; otherwise the patient dies of exhaustion after three or four or even six months. Many surgeons could not decide upon amputation, because they saw so many of those operated on die, and because if one did not amputate the patient lived a while and thus the good reputation of the surgeon was better guarded. What egoism! One should first do his duty and take the subject of good reputation into consideration afterward. Why allow a man to suffer for six months if he must die in the end? The surgeon must know how to decide; too much fear is often more injurious than rashness. Certainly one should not abuse operations, but he is culpable if he does not operate when the conditions demand it. If one would listen to certain writers there are almost no conditions which allow amputation; they consider it a painful remedy to be entirely banished by friends of humanity. Yet how easy it is to operate and to write. But, unfortu-

nately, a battle-field and a hospital have nothing in common with the ideas which an author in his study forms of them. Even out of love to humanity one must have recourse to great operations, and it is a very deceitful remedy which only too often allows people to die who might yet serve the fatherland and their families for a long time." For treatment of gunshot fractures of the lower leg metal boots with suspension were used (Ravaton), Petit's cradle (Bilguer) and pasteboard and splints (Schmucker).

A similar change from operative to conservative treatment in *gunshot wounds of the joints* was initiated. They had always operated until Bilguer and Ravaton taught to avoid the operation, and the latter in particular insisted upon the curability of those injuries in which the ball had only made an aperture without breaking the bone. The former said: "When a ball has passed entirely through the elbow or knee joint and thereby injured and shattered more than one bone we find no method of treatment safer than that by which we enlarge the wound sufficiently to loosen the pieces of bone properly in the most extreme cases and especially in the knee-joint, not even sparing the ligaments, but proceeding in respect to the further bandaging, as has already been suggested for shattered fractures of the bones." In spite of all, Boy would not admit that he had been mistaken and advised amputation in general for gunshot wounds of the joints with shattering of the bones, especially in case of the large joints. "Experience brings discredit upon all contradiction, the seeming improvement only deceives." If amputation were not allowed then the ligaments could be boldly severed, for why spare them? There was no danger in cutting through them; if the wound healed ankylosis resulted so that the ligaments of the joints were of no use.

In case of shot through the *shoulder-joint*, at first every hope for the preservation of the limb was abandoned (J. L. Petit, le Dran, Heister and Z. Platner), because the head of the joint was always thought to be fractured and the shock was said to be imparted to the entire bone. But E. Platner thought this concussion transmitted from the head of the joint not readily possible, "since in youth the head is separated from the shaft by a visible line of demarkation, and there is no fixed and immediate communication between the two. For although in maturity the two seem to be completely grown together, yet the lines of demarkation so apparent at an earlier age have not flowed together to such an extent that the head and shaft could be said to enter into a complete, unbroken union. Experience also teaches that the shaft is not necessarily splintered when the head is shattered." That was the same idea as Stromeyer's in regard to splintering above the edge of the epiphysis. Bilguer, Ravaton and Schmucker reported cures by the conservative method; in that way large incisions were not necessary as soon as one felt certain of suppuration in the joint. Gunshot injuries to the *elbow-joint* were regarded as more dangerous than those of the shoulder-joint, on account of the number of ligaments and nerves and of the many bony projections, inasmuch that amputation was looked upon as the rule. But in this case too conservative cures were more often reported (certainly by Paré). Ravaton thought that only those injuries offered a prospect of cure, which did not affect the entire joint, but nevertheless he would only amputate when gangrene and exhaustion threatened. Shots through the *wrist* were also cured but a stiff joint remained.

In *gunshot wounds of the knee-joint* with a simple capsular injury it was thought that amputation could be avoided (Ravaton); in those with shattered bones, lacerated ligaments or injury to the poplitea the rule prevailed to amputate immediately, the earlier the more successful (Schmucker and Boy).

The following, among others, were experiments in conservative treatment:

Ravaton (Obs. 90). The ball opened the capsule near the patella without injuring the bone. After three months, caries of the patella, amputation, death.

J. Hunter (Ausgabe von Palmer-Langenbeck, S. 890). The ball entered at the outer edge of the patella, went behind this through the joint and passed out through the cond. int. fem. Four days without treatment then superficial bandaging; cure.

Theden (Neue Bemerk. I Th. II Absch.). Shot through both condyles of the femur; extraction of many splinters. In the ninth week a fragment with a distinctly perceptible point penetrated into the knee-joint, and it was held down by graduated compresses and a specially constructed press. Without inflammation, suppuration or exfoliation ensuing, healing followed with a somewhat stiff joint.

Ehrlich (Chir. Beob. II Theil, S. 115). The ball entered at the condyl. ext. fem., passed through the knee-joint and out through the condyl. int. tibiae. French surgeons urgently recommended amputation on the battle-field. The patient consented; but as the knife was so dull that it was more like a saw, he rebelled. Allowed to lie helpless, on the following day he was brought into the hospital. The patient with a four-inch circular incision which reached to the muscles, now very earnestly desired amputation. However Ehrlich could not decide upon that because he had already successfully cured several similar gunshot wounds of the joints; banded with plaster. After six weeks the swelling, suppuration and synovial discharge had diminished considerably and in eleven weeks the wound was healed. The patient was discharged with a stiff joint in three months.

Boy (l. c.). The ball injured the knee-joint, the outer edge of the patella and the condyle of the tibia. For several days the patient was so well that Boy did not think of amputation at all. Then swelling, excessive suppuration in the muscles of the thigh and caries. Repeated incisions, injections and careful diet brought about a cure in five and one-half months.

Boy regarded as an exception his conservatively cured case of gunshot injury to the knee-joint, and considered amputation as the rule. He did not know that during the campaign gunshot wounds in the knee were survived without amputation, but he had observed many die when the operation had not been performed. Of course the amputation of the thigh was a dangerous operation, but patients endured it rather than that injury. "It can well be that a few amputations were made when the patient would have recovered without one, but many will be saved by amputations who would die without them. . . . What is very important in gunshot injuries to the knee, the amputation must not be postponed because it may soon become impossible to perform it successfully. The excessive suppuration which often extends even to the anus produces caries of the hip-joint and exposes the patient to the greatest danger."

If a cannon ball had torn off one of the extremities, the stump was amputated in order to make a simple and clean wound and to prevent inflammation (Mar-

tière). But similar injuries soon led to other principles. When an arm and shoulder-blade were torn off by a mill-wheel there followed no hemorrhage; a ligature was unnecessary and healing ensued (Cheselden). Ravaton saw an upper arm taken off close to the shoulder by a cannon ball; he bound up the artery, left the head of the humerus in place and thus avoided exarticulation; a cure resulted after seven months. Michaelis and Hunczovsky published two quite similar cases with ligature of the brachialis, the omission of amputation and ultimate healing. There were then submitted cures with and without amputation; one must take his choice. Bilguer was throughout opposed to a new amputation of the foot, lower leg, hand and forearm; he separated the ruptured soft parts still remaining, sawed off protruding ends of bones and removed all loose splinters. At the upper arm he made a ligature of the main vessels and in this way cured several cases; but in case of thighs shot off he saw, as a rule, death result so quickly from loss of blood that there was no longer any question of assistance. Schmucker also discarded amputation, and even considered it superfluous to saw off the ends of the bones, and he never observed severe hemorrhage follow because the arteries contracted quickly. When he found both upper arms taken off, the brachialis in only one needed to be bound; and even in case of the thigh the ligature of the femoralis was unnecessary. B. Bell and Larrey favored amputation, and also Richter, who however seemed to vacillate.

Whether one should amputate on the battle-field or later was a much discussed question. The older surgeons, Wiseman, Sharp and le Dran, had favored primary amputation. Faure in his prize work, declared this very dangerous on account of the increased sensibility and the anxiety of the patient, and would amputate only after three weeks or more, when the patients had recovered themselves. Boucher immediately opposed this view with some successful amputations made upon the battle-field (1756). Likewise thought B. Bell, Schmucker and the Siebolds, father and son, who would amputate immediately and even before transportation. These German surgeons frequently observed amputation of the thigh which were made on the first day heal, while if some days passed, and the wounded had been transported and inflammation, swelling and fever had arisen, the outcome was often fatal. Entirely opposed to this was the opinion of J. Hunter who, somewhat faint-hearted in his operative counsel, considered amputation upon the battle-field as the greatest mistake.

If hemorrhage did not indicate it at once he was willing always to postpone it until the inflammation was over, since the loss of a large limb, in perfect health and strength, was seldom endured. And if one should, with right, allege for the primary amputation that transportation is made more easily possible, yet experience opposes to this advantage that it costs more human lives than the secondary operation. These principles found a bitter opponent in Boy. He amputated as soon as the first shock was over, supported by the experience that in the field hospitals of the first class the operations always had the best results. Out of fifty-six amputations on the battle-field and upon soldiers treated in the hospital of Landau, fifty recovered. "If also many died whose limbs had been amputated on the battle-field, yet this does not throw aside the general experience. . . . Naturally, all those with fresh amputations did not recover. There

are patients who will die whatever we may do; again there are others who will come through successfully, however unwisely one may proceed. Any unnecessary postponement of amputation increases the danger. If inflammatory conditions once appear, the patient is killed by increased irritation; if suppuration is present he readily dies of exhaustion. If one must postpone the operation, he should watch the periods of inflammation and amputate at the time of the suppurative period." It is seen also that our intermediary period was also known in the last century and amputation was foregone during that time. Among the French military physicians, primary amputation now soon received general recognition, although one finds the name of Boy nowhere cited. The chief physician of the French army, Larrey, exercised the greatest influence with his rough notes from the battles of Napoleon I. (*Mém. sur les amput. des membres à la suite des coups de feu, 1797*). Percy and Sabatier joined themselves to him. The latter wrote to Larrey: "Citoyen! je suis pénétré depuis longtemps de la vérité que vous y exprimez, qu'il est nécessaire d'amputer sur le champ dans le plus grand nombre des cas, qui exigent cette opération." Larrey published a number of successful primary amputations and announced the following indications for it: 1, limbs carried off; 2, fractures with contusion of the soft parts; 3, laceration of the soft parts and main vessels; 4, fractures with laceration of the muscles and large nerves; 5, extensive exposures of the bone; 6, laceration of the bones, muscles and vessels without wider separation of the skin; 7, fractures of the joints of the foot and forearm, with laceration of the ligaments, and lodgment of a ball in the end or cavity of a joint, if it could not be readily extracted. Larrey considered a delay was indicated if gangrene was not yet limited, or if inflammation, fever and delirium appeared during the first twenty-four hours; then only could the secondary amputation come into question. He recommended conservative treatment in all simple fractures and in such as affected the joints.

(To be concluded next week.)

SOCIETY PROCEEDINGS.

Tri-State Medical Society of Alabama, Georgia and Tennessee.

Proceedings of the Ninth Annual Meeting.

(Concluded from last week.)

Dr. F. X. DERCUM of Philadelphia read a paper on

THE PATHOLOGY OF FUNCTIONAL DISEASES AS A GUIDE TO TREATMENT.

He described the nerve cells and related observations on cell activity in lower forms of life. These show movement of nerve cells and that activity causes the cells to shrink. Alcoholism causes serious nutritional changes in cells, especially that the fine prolongations were corroded, swollen and destroyed. There may be changes in cells, destruction of same and changes in the prolongations. Symptoms: Fatigue, irritability in keeping with pathology, loss of cell substance; may be due to poisons in blood. He related experiments with frogs. This is neurasthenia simplex, not that form found with organic diseases in pelvis, which is neurasthenia symptomatoma. The indications are: 1, rest and food; 2, removal of waste products. In hysteria, hypnotism should not be applied; may substitute worse condition; in insanity, rest, food, elimination of toxic agents. Autointoxication may come from: 1, excess of normal constituents; 2, due to diseased organs; 3, poisons from without.

Dr. J. B. COWAN emphasized the importance of the poisons in tissues.

Dr. R. M. CUNNINGHAM said that the experiments related wiped out the functional diseases. The pathology of the writer explains the symptoms and indicates the treatment.

Dr. L. S. McMURTRY said that nervous symptoms were often thought to be due to gross lesions. When these were removed the symptoms were not relieved. By elimination, rest and feeding, by improving the nervous system, they may improve.

Dr. G. C. SAVAGE related cases with pigeons which were killed in different stages of exhaustion, which showed that exhaustion reduced the size of the cell. We need not dispense with functional diseases. The changes are physiologic rather than pathologic.

In closing, Dr. DERCUM said that the essential in simple neurasthenia was fatigue, and might complicate symptomatic neurasthenia. To Hodge is due the credit of first making observations of cell changes.

Dr. F. B. SLOAN of Cowan, Tenn., illustrated "The Application of the Plaster Jacket and Dressings" on a subject on a frame by which the patient is to be suspended in a hammock while the jacket was applied. The patient was placed in hammock, which was supported by a roller around the body and around the top of the frame, and plaster jacket over hammock.

Dr. R. M. CUNNINGHAM had a case die just after suspension in the Sayre apparatus, in which there is severe shock after extension in Pott's disease.

Dr. SLOAN closed the discussion by relating three cases treated with the apparatus, which is the invention of Dr. T. W. Sloan of Seattle, Washington.

Dr. JOHN A. LARRABEE of Louisville, Ky., read a paper on

SOME POINTS IN THE TREATMENT OF TYPHOID FEVER

In which he claimed that as we are aborting other microbic diseases it is not unreasonable to attempt to abort typhoid. He thought that the products of the typhoid fever bacillus were far less injurious than the heterogenous microbes and ptomaines formed in the intestinal tract by reason of improper diet and from poisonous gases, the product of putrefactive changes, all of which are in our power to prevent. Intestinal antiseptics is the *sine qua non* of treatment. Avoid narcotics lest the already cloudy typhoid cerebrum should forget to preside over the function of life; may occasionally be used with restlessness, factitious and a dilated pupil, especially accompanying hemorrhages. Physical examination should be made every visit. Tympany should not be allowed to elevate above the spinous process. For this use:

R Ol. terebinth dr. j
Rochelle salts oz. j
Glycerin oz. iv

M. Inject one-half in pint of water, and remainder if not relieved in two hours.

He endorsed the principle on which Dr. Woodbridge bases his treatment, intestinal antiseptics. The essence of cinnamon is more potent to destroy micro organisms than carbolic acid. For thirty years he has never been without a pill made after the formula of Dr. Fisher, an army surgeon, consisting of crude mercury with aromatic oils and terebenthinates, cubeb, copaiba, peppermint, aloes and colocynth. When purgation ensued he alternated with 5 or 10 grains "Tully's powder." The annoyance of the fifteen minute dosage advocated by Woodbridge, he thought deleterious. He advocated specific treatment, *i. e.*, all intestinal antiseptics, which are innocuous, and had used guaiacol and guaiquin, especially where there is any probability of malarial complication, etc.

Hyperpyrexia is important but must be overcome by means not prejudicial to the patient. When the temperature persists at 104 degrees, use thirty drops externally to a small area of the abdomen. Never use antipyrin or acetanilid. If pulse and temperature rate are greatly disturbed, use small doses of strychnia.

It is a question whether the enforced feeding of the present day is not as deleterious as the venesection, almost to exsanguination, of former days. Complete anorexia helps to make early diagnosis. Bouillon, Axtell's capsules, buttermilk, Mellin's food with milk and plenty of sterilized water are quite sufficient to choose from, and never more than a gill at a time. He protested against the use of alcoholic stimulants. He had never seen any benefit from their use which could not have been obtained from tea or coffee. Digitalis has no place in typhoid. Strychnia is the one heart stimulant to be used. He should not wait for urgent and alarming symptoms before giving small doses. Whenever the pulse and temperature are disturbed in the relation of 10 to 1, strychnia should be used. Heat is a powerful stimulant to the heart and a hot water bag or Geyser hot appliance should be at hand for emergencies. Hemorrhage is from super-alkalinity and defibrination of the blood by the ptomaines formed in the intestinal tract. In some, hemorrhagic diathesis; increased coagulability in some. This condition is favored by mineral acids and especially a diet of

buttermilk, lactic acid, better safeguards against hemorrhage than hemostatics. Ergot controls bleeding only when unstriated muscular fibers can compress the vessels; in other forms of hemorrhage a therapeutic error. Antiseptic treatment is of value not from destruction of bacilli, but from prevention of formation of ptomaines and poisonous gases, which are main factors in keeping up disease. Typhoid is a swallowed poison, hence the importance of pure water. Nothing equals chlorinated lime for disinfecting the dejecta. It is as criminal to deposit the non-disinfected stools in a vault or cesspool as to put Paris green in a neighbor's well.

Dr. J. W. DUNCAN said that the author was in accord with his views. For some years he has believed that typhoid fever could be aborted and had been using the best antiseptics obtainable. About two years ago he got Dr. Woodbridge's formula from Parke, Davis & Co., and had gotten good results in every case: had not lost a case since. He agrees that the patient should not drink well water; had not seen a case in last five years who did not drink well water. He also believes that the disease may be caused by using milk from cows that are allowed to drink impure water. He sustains patients with strychnia, careful feeding with liquids only.

Dr. G. W. DRAKE said that in Chattanooga there was very little typhoid since improved sanitary condition, sewers and water-supply. Would treat with baths, not as Brand, but at such a temperature as would not shock the patient. This was enjoyed by the patient. Accomplishes good not by reduction of temperature but by application of water.

Dr. J. Q. SUTTON stated that he had used Woodbridge's treatment three years, but that when he began to purge he dosed less often. In Tracy City those who used cistern water did not have disease, but those who had the disease used well-water.

Dr. J. A. WITHERSPOON said that the poison is not in the bowels but formed in the lymphoid tissue, hence intestinal antiseptics is not rational. The disease frequently reported as typhoid was not typhoid but a hybrid fever due to intestinal fermentation.

Dr. J. B. COWAN had not seen a case of typhoid for twenty years.

Dr. JAMES E. REEVES of Chattanooga had examined 300 cases and did not find the Eberth bacillus in one. The fever we have may be due to intestinal fermentation, and here intestinal antiseptics may be useful. Hemorrhage may be due to hypermedication.

Dr. ANDREW BOYD said that Dr. Cowan had discussed this disease at every meeting for ten years and had always advocated whisky, and he wondered that he had not mentioned it. Dr. COWAN replied that he was coming to that when his time was out. He gave whisky in every case of fever.

Dr. WILLIAM R. BLUE of Louisville, Ky., read a paper on "The Cystoscope in the Diagnosis of Bladder and Kidney Disease," with presentation of the Leiter-Brenner cystoscope, which he preferred. He related cases in which it had been used for foreign bodies, stone, tuberculosis, etc. The cystoscope is indicated in obscure urinary troubles and to aid in catheterizing the ureters.

Dr. W. FRANK GLENN said that the value of a cystoscope and endoscope could be appreciated only by those who used them. Stone can be diagnosed where not found with sound. He related a case where stone had been found postmortem which could not be found with a sound. In all obscure cases the cystoscope should be used. It is extremely difficult to catheterize the male ureter.

Dr. BLUE said that many condemned the instrument from want of skill in using it. This requires plenty of patience, skill and glycerin.

Dr. J. P. STEWART read a paper entitled "A Bouquet of Remedial Agencies," which was a discourse on the moral management of patients. He related a number of cases relieved of serious nervous troubles by giving way to their whims and thus securing their confidence; dealing on the influence of the mind over the body and the influence of one mind over another.

Dr. W. FRANK GLENN said that the subject of the influence of the mind over the body and over another mind was full of interest. The first duty of the physician was to get the confidence of the patient and then his suggestions would pretty surely be realized by the patient. Nineteen hundred years ago Jesus had taught this law every day, that the cure depended on the confidence of the patient. "Thy faith hath made thee whole."

Dr. G. W. DRAKE believed that every disease had a material basis. There are no imaginary diseases. Mind may act on the cell but has not complete power. In these cases give medicine and use suggestion.

Dr. E. B. SANGREE said that the paper was especially inter-

esting, as it dealt with a subject out of the general run. Since we are as ignorant of the ultimate constitution of matter as we are of mind it is well to be cautious in the use of the word. We know there are trophic nerves, and if nervous influence can affect cell metabolism it follows that anything that can stimulate nervous impulse can affect cell metabolism favorably. There is consequently no inherent reason why material effects can not be produced by mental action.

Dr. J. P. STEWART, in closing, mentioned a hysterio-epilepsy of ten years' standing, where the convulsions were stopped in three minutes when otherwise they would last thirty six hours. He suggests no return for a week; later, for a month. Has had no convulsion for five years.

Dr. LOUIS FRANK of Louisville, Ky., read a paper on "Hysterectomy; Is it Justifiable in Septic Diseases of the Appendages?" He believes vaginal hysterectomy a fad. The reason assigned is that the uterus after oophorectomy is a useless organ, when the fact is that it is necessary to complete the pelvic floor. It is not more liable to gonorrhea, tuberculosis and cancer than before. He regards the operation as more dangerous than removal. There is less shock in abdominal operation without removal of uterus; position of bladder not disturbed. Total extirpation may not be necessary; less danger of tearing. Does not oppose vaginal hysterectomy for cancer but only in rare cases.

Dr. L. S. McMURTRY said that a limited number might be cured by tapping. The French are experts in vaginal hysterectomy, but are not equal to the Americans and English in abdominal section. The best surgery is that which cures the patient thoroughly and completely with the least mortality and preservation of most of the organs in their integrity; can not make accurate diagnosis, especially as to bowel involvement if uterus is sacrificed before complete diagnosis. Often suppurating tubes, etc., are not removed. Convalescence is retarded by slough from clamp; not a completed operation. In abdominal section we can drain *per vaginam* or above by suction. The personal equation of the surgeon cuts an important figure, but generally the abdominal route is best. Cases can be cured both ways.

Dr. W. D. HAGGARD, JR., was an American convert to the French school. He would not remove a healthy uterus. Where both tubes are infected the mucous membrane of the uterus is infected, then the uterus should be removed or it may be reinfected, necessitating subsequent operation. The reason for vaginal hysterectomy is on account of less mortality. The advantage is that we can break up adhesions and abscesses by fingers, *per Douglas cul-de-sac*, and determine extent of operation necessary.

Dr. R. M. CUNNINGHAM said that a thorough curetting of the uterus occasionally cured pus tubes. Removal of pus tubes *per abdominal section* and thorough curetting of uterus meets the indications.

Dr. B. SHERWOOD DUNN cited statistics showing that the mortality by the vagina was better. Since coming to America he had changed his mind. Vaginal hysterectomy had been pushed to extremes in Paris and there will be a reaction. He will operate by abdominal route in many of his cases hereafter. Vaginal hysterectomy will not be superseded in peri-uterine abscess and cancer. In bilateral pus tubes he would perform abdominal section. He had never had secondary infection in 500 cases.

Dr. G. W. DRAKE of Chattanooga, Tenn., read a paper on "Abnormal Metabolism," insisting on importance of proper nutrition. Disease is due to change which may not be seen even with the microscope. The animal extracts will largely supersede other remedies in future.

Dr. L. B. GRADY of Nashville, Tenn., presented a case where there had been "Infectious Disease of the Brain from Acute Suppuration of the Middle Ear." Infectious disease of the brain, from chronic suppuration of middle ear is quite common; may have pachymeningitis, leptomenigitis or abscess of brain. In this case the inflammation was from the use of the douche. The membrana tympani was punctured but abscess of mastoid resulted. Nearly the whole of the mastoid was removed, followed by abscess of the posterior part of the middle lobe. Operation was followed by recovery.

Dr. N. C. STEELE emphasized the danger of using the nasal douche. Mastoid operations are successful as a rule. He insisted on the importance of opening mastoid when pain in this region was not relieved by leech and hot applications.

Dr. FRANK TRESTER SMITH called attention to the lesson of the importance of middle ear disease as a causative factor in producing brain lesions, especially abscess. As a rule abscess of the brain is caused by suppuration of the middle ear and hence it is important that the latter be cured.

Dr. C. M. DRAKE of Atlanta, Ga., read a paper on "Formal-

dehyde as a Disinfectant." He endorsed the use of this agent, which has the support of the Marine-Hospital Service. He described the lamp devised by Kinyoun, which is simple, cheap and effective. It is the most feasible and best germicide for disinfection. Trunks are to be filled with the fumes and placed in a room filled with the gas. The gas is very irritating to the eye, nose and throat.

Dr. J. A. GOGGANS related a case of ptomain poisoning (probably), due to eating oysters, with symptoms resembling atropin poisoning.

Dr. G. W. DRAKE said that urticaria was often the result of diet and medicine. He knew of cases due to eating strawberries.

Dr. GOGGANS said that it was not a case of urticaria, there was no itching.

Dr. DRAKE said the cause was similar and the treatment should be the same.

Dr. J. W. HOOPER said it was difficult to decide whether it was due to poison or reflex trouble. Patient gives history of similar trouble whenever he eats cheese. He thought it one of tyrotoxic poisoning.

Dr. J. W. HOOPER of New Site, Ala., read a paper on "The Practical Application of the Microscope to Every-day Practice," relating cases where renal colic was diagnosed from appendicitis by examining the urine. The microscope should not be relied on exclusively. In an epidemic of diphtheria he found the streptococcus and gave an unfavorable prognosis. Many of the cases died.

Dr. R. M. CUNNINGHAM thought that the general practitioner should be able to count the blood corpuscles and estimate the amount of the hemoglobin. The microscope in the early diagnosis of tuberculosis is of questionable importance. The average practitioner will not give the time to recognize what he knows.

Dr. RICHARD DOUGLAS of Nashville, Tenn., related a case of a woman at full term with placenta previa and contracted pelvis two and three-fourths inches, hemorrhage increasing, and asked what the members thought the proper procedure.

Dr. J. B. COWAN suggested dilatation and delivery.

Dr. G. W. DRAKE co-incided; could not see that anything could be gained by waiting; craniotomy if necessary.

Dr. J. W. DUNCAN would advise, if pelvis large enough to deliver head, immediate dilatation, version and delivery as rapidly as possible. To attempt to apply forceps above the brim of the pelvis might cause delay, which would result in the death of the mother as well as the child. If the deformity precludes the possibility of natural delivery he agreed that Cesarean section is the thing to do at once.

Dr. J. A. WITHERSPOON said that it was impossible to deliver head at two and one-half or three-fourths inches, and the case should be watched and Cesarean section performed.

Dr. C. M. DRAKE recommended symphysiotomy and immediate delivery.

Dr. DOUGLAS thought the indications clear. In placenta previa deliver immediately, always. The high forceps operation is difficult and dangerous and his plan of procedure will be Cesarean section.

The meeting was one of the most successful ones in the history of the society, scientifically and socially. The evening of the first day was spent at the Centennial Exposition and also the afternoon of the second day, when the physicians of Nashville tendered the visitors a luncheon at the Lion Roof Garden. About 200 members and their ladies were present. The X-rays were exhibited at the close of the night session of the second day showing bones, foreign bodies, deformities, etc.

The following resolution was passed:

Resolved, That the recent outburst of yellow fever in the South and numerous conflicting State and municipal quarantine regulations, emphasize the great need of national quarantine laws which are uniform and protective; and

Resolved, That the Tri-State Medical Society in convention assembled urge upon members of Congress the need of laws governing quarantine in the development of cholera, fever, smallpox and plague.

The Society will meet in Birmingham, Ala., next year. The date will be selected by the Committee of Arrangements.

The following officers were elected: President, J. A. Goggans, Alexander City, Ala.; vice-presidents, Andrew Boyd, Scottsboro, Ala., G. W. Drake, Nashville, Ala., and C. M. Drake, Atlanta, Ga.; secretary, Frank Trester Smith, Chattanooga, Tenn.; treasurer, Geo. R. West, Chattanooga, Tenn.; chairman Committee of Arrangements, George S. Brown, Birmingham, Ala.

Let us have a Department of Public Health!

SELECTIONS.

The Pest-Stratum of the Sites of Cities.—Dr. Robert Barnes, who as long ago as 1855 was a health official for a part of London, in *Sealpel*, treats of the dangerous properties of the superficial soil of cities, the careful future investigation of which will solve some of the mysteries of high civic mortalities. We agree with him that we do well to labor with the outstanding problems of water-supply, but as they will presently be mastered, the problems of the soil will become urgent and, as they too are solved, life-saving will begin in good earnest. Dr. Barnes says: "One of the most striking examples of the influence of soil, and soil governs water and air, is the generation of ague. Ague was at one time endemic in Shoreditch, but it has vanished. So we may reason that unhealthy sites may be made healthy by care; but it is not less true that sites, naturally the most salubrious, may by neglect become pestiferous and deadly. I showed that we were chiefly concerned with the soil to the depth of thirty feet. Proceeding from the surface we had a bed of variable thickness, commonly called 'made earth.' It is chiefly an artificial stratum. The proportions of 'virgin soil' to that of common earth had been reduced to a very insignificant amount. The great bulk was made up of refuse of every kind. . . . This upper stratum so constituted had been further polluted, and its noxious qualities intensified, by innumerable perforations for cesspools, and constant saturation from defective sewers and drains, the poisonous emanations from gas-pipes, and every conceivable abomination resulting from the off-scourings of a population of 25,000. This layer of foul stuff, or pest-stratum, as it may appropriately be called, varied in thickness from one or two to sixteen feet or more. This description of the pest-stratum is a very important contribution to geology. This last stratum, the work of man, has to be cleared away. This done, geology reverts to its primeval natural purity. Another observation may be pardoned. If this pest-stratum, laden as it is with putrescent matter, could be kept dry, it would be comparatively harmless. Moisture is a necessary element for the evolution of its pestiferous properties. Hence good surface drainage is not less necessary than deep drainage. And we may see a happy illustration of this in the present condition of the city and the more perfect districts of London. The paving and other means for securing quick surface drainage not only lessen the emanation of foul air from the surface, and from the soil beneath, but they also promote the dryness of the air. The relative humidity of the air in London is often less than in the country. This is especially marked at night. There is little or no dew. The dry surface gives off no moisture for precipitation. And so we get in London the luxury of clear, dry, fresh air at night to a degree hardly known in many parts of the country. Doctors who have experience of night work have found this out. A practical lesson from this is: That windows may often be opened at night in London with benefit, when in the country, where grass is near, the practice is fraught with danger. I have had many proofs of this in country consultations. To secure this surface drainage and cleanliness to the greatest extent it is essential that the material for pavements be solid and impermeable to moisture. Flagstones and asphalt fulfil these conditions. Wood pavement, pleasant as it is in some respects, does not. It absorbs damp filth and gives off foul air and dust. The population actually living on the bosom of the Thames, whose every breath is a distillation from its water, is not especially liable to fever; not so much so, indeed, as the population whose dwellings skirt the banks. And this littoral population, it must be borne in mind, is exposed not only to the malaria arising from the banks, but also to that same class of pernicious influences attached to bad sites and badly constructed houses, which are found alone sufficient to generate

fever. Few of the seamen who filled the medical deck of the *Dreadnought* contracted their illness on the river under circumstances which can be connected with the state of the waters; and of these few it will be found that the illness of most could be traced to cold, wet, exhaustion, bad food, drinking bad water, and overcrowding in the close ill-ventilated forecastles of unhealthy ships. Most erroneous assumptions still continue to guide the exertions of those who are most earnest in favor of the present scheme of what is called the dissipation of the Thames. I had studied the Gulf Stream as it flows in a distinct current across the Atlantic; I had seen the Plata propelling its stream of fresh water unmingled many miles into the ocean; I had traced the confluence of the Rhine and the Main, whose streams are colored, one red, the other green, running on side by side, two rivers in one bed, and I concluded that the great sewage stream would hold its course, a concentration of pollution. Sir John Simon, in his admirable reports, expressed conclusions in harmony with the above and with the evidence adduced in my observations on the Thames, read before the British Association at Dublin. In this memoir, based upon examinations of the Thames water, of which samples were taken weekly during a whole year, at high and low water, from alongside the *Dreadnought*, I was assisted in the chemic side by Odling, and Hassall in the microscopic side. During the construction of the easternmost main sewer I had an opportunity, I will not say of enjoying, but of experiencing a festivity under conditions which few excepting professional sewer-men, can appreciate. I accompanied a committee of my Vestry and the surveyor in an official survey of the sewer. We descended into this subterranean canal by a hole near St. Luke's Asylum, walked along as best we could, breathing the balmy sewerage air, to a point at the East end of London, where we emerged. It is needless to say that as a safeguard against accidents, we took with us a supply of alcohol; and, to make our visit and report more picturesque, we stopped on our way and had lunch with what appetite we could muster. This experience taught us, I hope, to look with indulgence upon the occasional breach of the law of temperance by professional sewer-men. On coming into the free air above I felt as I fancy Dante felt on passing from the Inferno into Paradise. No one was the worse for the adventure."

Ambulant Treatment of Fractures of the Leg.—Dr. C. Walther, in the *Revue d'Orthopédie*, has made a critical study of the methods which have been tried by German surgeons to secure the use of the legs in standing and walking during the process of healing in fracture. In the first place, he takes exception to the term "ambulant treatment," and suggests "treatment by action" as contrasted with "treatment by rest." The question is, is it possible to enable one to walk usefully who has an united fracture of the leg or thigh? (By "usefully" meaning the resumption of work, sitting or standing.) The apparatus must be so arranged as to take from the lower segment, below the solution of continuity, the pressure from the weight of the body. The apparatus used by Korsch and Bardeleben was first applied to fractures of the malleoli and leg, and afterward to osteotomies and resections. The principle on which they were employed was that of continuous extension, first made actively while putting on the plaster bandage, second passively continued by the apparatus. The writer, in the *Revue de Chirurgie*, 1895, had shown that continuous extension could not be exercised except by elastic bodies, or by the action of a weight; by any other means it is intermittent or illusory. Burns' orthopedic apparatus is the one most widely known; it consists of a plaster bandage to which are attached two hollow tubes fastened above at the root of the thigh to a padded metallic ring, taking its point of support at the ischium. Below, a stirrup fixed two or three centimeters below the plaster sur-

face of the foot, maintains the foot above the ground while standing. Bardeleben enumerates the following claims for the new treatment: It would prevent the formation of scars, antagonize atrophy of the muscles, hasten formation of the definitive callus, keep the organism in good physiologic condition, and give great help to the aged, to alcoholics and to all with debilitated constitution.

1. All kinds of apparatus, however delicately applied, can produce scars by pressure on the point of support, or by some disturbance of nutrition from other cause. If this is so when the patient keeps his bed, the limb is immobile and nutrition is least disturbed, how impossible to avoid it when the limb is down and circulation and innervation are interfered with by pressure much more considerable.

2. The pressure inward on the tissues by the padded ring and outward by the consequent edema, interfering with circulation, will more than neutralize the good effects of muscular action; besides, action itself is refused if it can not take place without suffering.

3. The definitive callus is formed only after five or six months when the apparatus has already been taken away. Whatever increased nutritive gain to the fragments there might be in the increased activity, would be counterbalanced by the more frequent displacement of the contiguous ends of the fragments, this being known to be the most fruitful source of fibrocartilaginous union, thus postponing indefinitely the definitive callus.

4. The restraints within doors are about the same, because the treatment does not admit of resuming the usual employment.

5. Alcoholics suffer from delirium tremens too soon after the accident to be benefited by the apparatus, which is not applied till between the eighth and fifteenth days.

The points of support on the thigh must be the skin, the muscles and the bones. The skin in its intolerance to continued pressure, in its elasticity and in its mobility over the subjacent parts coated with the secretion of its numberless glands, would never be anything but an uncertain and intolerant point of support. The appliances to its wrinkling surface would cause suffering, phlyctenulae, excoriations and scars. In the leg the gastrocnemius is the only support for an apparatus applied to the muscular tissue. If it is utilized its skin covering must participate, the muscle will atrophy and, at best, the force will be applied at the point of insertion of the tendo Achillis in the calcaneum so as to exert pressure upward on the lower segment of the fracture, the very thing sought to be avoided. As to the bony supports: The first indication is to maintain the foot above the ground by means of protectors embodied in the plaster bandage. The second is to find, above the solution of continuity, points of solid support on the bones of the leg or pelvis. There are only the tuberosities of the tibia in the leg. The condyles of the femur project too far for the tibial region; and it is out of the question to employ the patella because of its mobility. Besides, the skin would be intolerant of an apparatus applied over such sharp angles as those of the tuberosities of the tibia. The ischia offer better support when the fracture is above the knee, being solid, protected by a thick pad of cellulo-fibrous tissue imbedded in fat, which lessens shock and pain from pressure. But, with all this favorable, the most delicate skill in application would be needed as well as the most expensive materials, to utilize this point of support successfully; and there would still remain the danger of ankylosis of three large joints, besides the risk to be taken in interference with circulation, to edema, scars, etc.

The author believes that few, except transverse fractures of the leg, could be benefited by the "ambulant treatment." In the aged, in children, in most women and in fat, over-muscular or too feeble men, it would be contraindicated, or impossible. He sees in this method no real advantages as to definite results; he thinks it impracticable, for to apply suitable apparatus,

exceptional skill would be needed to secure proper traction on the parts and permit use of the limb in walking. Besides, the cost would bar it from those most to be benefited by it. His conclusion is: To hope to enable those with fractured femur or tibia to walk usefully before consolidation, is at present a beautiful dream whose future, however desirable, can not yet be foreseen.—*Clinical Recorder.*

Imperforate Anus Treated by Kraske's Operation; Recovery.—Dr. Matas, in the *New Orleans Medical and Surgical Journal*, records a successful operation for the relief of congenitally imperforate rectum in a well grown male infant. The operation was done forty hours after birth, without anesthesia. There was no loss of blood, no blood vessels having been encountered. The infant went to sleep soon after the conclusion of the operation. A cough, the prodrome of pertussis, which was epidemic in the locality at the time, was noticed on the day following the operation. This complication seriously threatened the final success of the operation. The serious nature of the case was fully explained to the parents and an operation urged that would permit the establishment of an outlet through the normal anus or perineum, or of an artificial anus elsewhere, if the exploration of the pelvis revealed such a condition that made the restoration of the intestinal canal at the anal region an impossibility. The parents at once consented. The general condition of the baby was excellent. The abdomen, though slightly full and tense, did not give evidence of intestinal paresis. The stomach retained a few teaspoonfuls of sweetened water without vomiting. The frequent paroxysms of violent cough unquestionably precipitated a complication which would at least not have presented itself so soon after the operation. In consequence of the large pelvic outlet in the sacro-coccygeal region and the laxity of the anal orifice from weak sphincter control, the rectum began to protrude, and not many days elapsed before three inches of prolapsed rectum remained constantly extruded from the anus. All attempts to control the escape of the bowel failed. The constant protrusion of the rectal mucosa caused irritation and tenesmus, which distressed the child exceedingly and prevented rest. None of the local applications had the least influence in preventing the recurrence of prolapse and it became necessary to operate. "Having no faith in the palliative operations in such a case, I decided to excise the prolapse. Therefore, twenty-eight days after the first operation, I amputated three inches of protruding bowel. After finishing this operation, we found it necessary to circumcise the child on account of phimosis, which made urination painful. These operations were followed by no unpleasant consequences, and in ten days the child was entirely well, with the exception of an incipient inguinal hernia, which became less troublesome as the cough diminished. It is also worthy of note that, in addition to the anal defects, the phimosis and the disposition to hernia, the child was born a unilateral cryptorchid, one testicle having failed to reach the scrotum. After this event the child continued to grow and do well, though he has always been pale and not as vigorous as his other little brothers. About a year and a half after the operation, the baby was brought to the city and I had the opportunity of examining it. The child had normally three or four bowel movements a day. It was difficult to ascertain whether there is much bowel control, but the finger feels a certain amount of resistance and contraction when it is introduced a short distance beyond the anal margin. The baby appears to be disposed to frequent diarrheal and dysenteric attacks, which are probably due to digestive disturbances. When these occur, the anal region becomes irritated, and has to be most carefully washed to prevent eczema and excoriations. It is also noticed that under these circumstances there is no fecal control. There is also a tendency to recurrence of the prolapse.

sus recti, though in a much less degree than when this condition first existed. The prolapse now appears to be due to the tenesmus of dysentery. It is probable that the operative treatment will be required if the prolapse continues to increase. If such is the case, I shall advocate a simple rectopexy or anchoring of the rectum by Verneuil's method. While the child has thus far survived, and is apparently in very fair condition, it is evident that it has had to travel over a very hard road, and that its future path is not likely to be strewn with roses. After a careful investigation of the literature of the subject, I find that this is the tenth in a list of twelve cases of ano-rectal imperforation in which relief has been attempted by Kraske's method or its modifications." The cases are reported by Vincent of Lyons, two cases, in 1887; Ceci of Genoa, 1890; Burrell, Boston, 1891; Chaput, Paris, 1892; Poisson, Nantes, 1892; Czerny, Heidelberg, 1893, two cases; Fochier, Lyons, 1894; the present case, New Orleans, 1894; Elliott, Boston, May, 1896; W. W. Keen, Philadelphia, December, 1896. Of the twelve cases reported only two succumbed to causes directly connected with the operative treatment, and in one of these death was caused by peritonitis due to the infection of the peritoneum with an exploring needle previous to the sacral operation (Czerny's second case). Eight out of the twelve cases died at variable periods, from a few days to two months after the operation, from diarrhea, marasmus, capillary bronchitis, and other conditions not directly connected with the operation. Four of the twelve cases had survived up to the time when they were reported: in Burrell's case, four and a half years after operation; in Poisson's, three years; in the writer's case, two years and nine months; in Elliott's case, six months after the operation.

Resume of John Howard's Sanitary Labors.—The editor of the *Scalpel* closes a long essay on the life and deeds of the great Howard with a digest of his sanitary efforts. He says: John Howard had no sort of sympathy with crime or criminals, but a sense of justice, a submission to duty, a moral and physical courage, an industry and perseverance, a truthfulness, simplicity and modesty, which never before met in the same man, and probably will never meet again. He was emphatically one of those Englishmen to whom, if I may use the grand patriotic language of Milton, "God, when he would work some great reformation, does as his manner is, first reveal himself."

Such a life if written would have to deal with the poor in prison and the sick in hospitals. It would be a tale of human suffering, but the moral would amply compensate for the painful details necessarily brought before the reader. It should be treated as Dr. Guy says, as a romance: a romance which shall to the end of time amuse and instruct, reprove and encourage, not those only who speak the language that Howard spoke, but those, too, all the world over, who are able to appreciate the magnitude of the evils that he attacked, and the greatness of the victory which he won.

Howard's labors were truly Herculean. We can hardly realize that it was in the physical power of one man to do so much work. In his mission of charity he traveled over 45,000 miles, and went through hardships and perils of the most trying kind. Fortunately, he was spared to write out the history of his travels. Howard's explorations differ from those of Livingstone, Speke or Burton. They were of a nature which would only attract a man animated by the highest and purest feelings of humanity. They would be repellant to an ordinary mind. To live in an atmosphere of crime and misery, to have to descend into the miserable cells and dungeons described by him in his "State of Prisons," to have to witness the revolting cruelty and the unkindness of man to man, were duties which few would be capable of undertaking. Howard suffered from the very sufferings he had to witness, and from his want of power of being able to redress them. He visited in Ireland fifty

prisons and goals. Out of that number he found five clean and forty-five dirty. It will be noticed that the Scotch prisons were in an equally insanitary condition. Howard attempts to explain this. He says that the original cause of this seems to have been the following very severe maxim in the Scotch law: After a debtor is imprisoned he ought not to be indulged the benefit of the air, not even under a guard; for creditors have an interest that their debtors be kept under close confinement, that by the squalor carceris they may be brought to pay their debts. He visited in Scotland twelve prisons and goals, and found none clean and twelve dirty. Howard has left us an almost equally unfavorable picture of the state of English prisons. He visited in England 253 prisons and goals, and found ten clean and 243 dirty. He visited 108 prisons and goals abroad and found the majority of them clean. I have laid it down as the experience of Howard that dirt and disease went together, so that the health of prisoners depended in a great measure upon cleanliness. We can form a very easy approximation of the value of Howard's sanitary reforms from one disease alone, gaol fever. It is a disease unknown at the present day in connection with prison life; it was but too well known in the days of Howard, not only in England but on the Continent. Taking Howard's figures we may agree with Dr. Guy that the disease haunted one-fourth at least of our goals. On the hulks on the Thames, amongst the prisoners, the disease seems to have been most destructive. "From August, 1776, to March, 1778, 176 prisoners died out of 632. This is more than one in four." Taking this as an estimate we may make it the basis for the number of lives he has been the means of saving, not alone in England, but over the whole civilized world.

For the purpose of comparison it is unnecessary for me to state the number of prisoners who are confined in English and foreign prisons at the present moment or who have been confined during the past fifty years. As population has increased, and as crime unfortunately preserves an equal ratio of increase, we may assume that there are more prisoners now than there were in the days of Howard. The gaol fever is now extinct. It has been stamped out by man's agency and by attention to the elementary laws of health. If one in four died in the time of Howard of gaol fever, and none die at the present day, what a vast saving of life has been effected. Every life saved must be credited to the great prison reformer. If we only take the prison returns of fifty years the net gain in life would reach a goodly roll. By attention to hygiene, to construction and arrangement of prisons, our prisoners have been saved from the gaol and other fevers, and by the humane management of prisons now adopted, prisoners are not only saved from disease but preserved in a state of health.

PRACTICAL NOTES.

The Application of Collodion and Salves in Ophthalmology is much facilitated by using a glass stirrer with a rounded tip. The substances do not adhere to the glass, and it is easily sterilized, while the smooth, rounded surface can not injure the eye.

Strychnin in Chloroform Poisoning.—In a desperate case of voluntary poisoning with chloroform, after the failure of all other means, the patient was restored by injecting, several times, about three centigrams of strychnin, seconded by artificial respiration and electricity. No deleterious effects were noted.—*Semaine Méd.*, December 15.

Convenient Method of Preserving and Diluting Tuberculin.—To avoid wasting the expensive substance when small injections are required, Tuwim fills a Pravaz syringe with the original tuberculin and stands it upright in a glass with the hole in the needle stopped with a soft cork, all under the strictest aseptic

precautions and protected from the light. When needed, the tuberculin is squeezed out, one drop at a time, and the consistency is such that the quantity in each drop can be calculated with great accuracy.—*Deut. Med. Woch.*, December 2.

To Differentiate the Grippe in Deceptive Cases.—A drop of blood is drawn from the finger into a tube, which is closed with a little cotton and laid away for twenty-four hours. At the end of this time the blood has become converted into a culture of the diplo- and strepto bacilli characteristic of the grippe, extremely motile and easily visible with an ordinary microscope, 600 to 700 diameters. If negative results are obtained in twenty-four hours repeat in forty-eight.—T. V. Coronado in *Revista de Méd. y Cir. de la Habana*, December 25.

Indigo-Carmin Test for Milk.—If a few drops of a solution of indigo-carmin are added to milk the tint produced by it vanishes as the action of the microbes in the milk decolorizes it. The length of time the milk has been standing can therefore be determined by the duration of the tint; the older the milk the briefer the period of coloration. In fresh milk it lasts about twelve hours at 15 degrees C.; five hours at 15 to 20 degrees and four hours at 20 degrees, while it vanishes almost instantaneously when there are several decigrams of lactic acid to the quart.—Vaudin in *Bull. de l'Acad. de Méd.*, November 30.

Pyramidon.—The value of this new form of antipyrin (*vide* JOURNAL, Vol. 29, page 1318), is confirmed by the results announced from v. Limbeck's clinic where it has been tested in a hundred cases of various diseases. Its antipyretic effect in chronic tuberculosis was highly satisfactory in thirty-two cases out of forty, and it was so successful in nine cases of articular rheumatism that it is recommended as a substitute for salicylic acid whenever there is intolerance. The fever not only subsided but it seems to have a specific effect on the rheumatism, 1.5 gram in fractional doses during the day. Its analgesic effect was also striking in migraine, trigeminus neuralgia, and other nervous pains, for which it is especially recommended. The effect is slight in chronic rheumatism, negative in malaria and nervous tachycardia and there was intolerance in two tuberculous patients.—*Wien. klin. Woch.*, November 4.

Prolapsus of the Female Urethra.—This trouble is rare (100 to 120 cases on record). It sometimes occurs during a coughing paroxysm in pertussis. Various methods of treatment have been devised, but the use of the knife is frequently followed by stenosis, and by death in one case. Emmet's "buttonhole" is not advisable on account of the fistula left and the double operation. Kleinwächter's method of slitting the urethra and suturing the beginning of the prolapsus to the base, is only applicable to partial inversion, but Israel's method is effective, simple and permanent in its results, as Wohlgenuth has confirmed recently, describing his experience with it in the *Deutsche Med. Woch.* of November 4. The protruding mucous surface is cauterized in narcosis with the Paquelin in a radiating series of burnt strips lengthwise of the urethra, through the entire thickness of the mucosa. The cicatricial contraction that results puts an end to the prolapsus. Two applications were necessary.

Minor Points in Gynecologic Technique.—After vaginal hysterectomy Bélin applies tampons in three layers; aseptic, aniline dyed strings are fastened to each tampon, a different color for each layer, so that one layer can be removed and replaced at variable times without disturbing those that should remain undisturbed for longer periods. This trifling innovation, he states, has rendered him inestimable service during the last year. He also uses a cone-shaped cake of soap in making the toilet of the vagina, which does not slip out of the hand like the ordinary cake and get lost in the depths. Reverdin's further improvement consists of a tube passing through the cone-shaped cake of soap, which fits into and closes the orifice of

the vagina, while the water passes through and distends the walls. We note *en passant* the increasing tendency evidenced at the last French Congress of Surgery to prefer the abdominal route for hysterectomy.—*Journal de Méd. de Paris*, December 19.

Olive Oil in Hepatic Colic.—Barth reports the successful result of the administration of large amounts of olive oil in two cases of hepatic colic with icterus, caused by incarcerated gallstones. In one case 200 grams were taken every other day, and in the other 150 grams each day, the taste improved by a few drops of essence of anise. Part of the oil was found in the feces in a saponified condition, in the shape of small green particles which were at first erroneously supposed to be fragments of the gallstones. The rest was split into stearic acid and glycerin. The oil, besides lubricating the mucous surfaces and thus facilitating the expulsion of the stones, excites powerfully the secretion of bile, which flushes the biliary passages and removes particles that might ultimately develop into stones. On account of the increased secretion of bile, oil affects the system injuriously in adhesive cholecystitis, and it is also useless in dilatation and ascending suppurating infection of the biliary passages, and even injurious, on account of the impaired digestion and extra work forced on the liver.—*Semaine Méd.*, Dec. 1, 1897.

Improved Method of Sterilizing Catheters.—H. Alapy has perfected his method of steam sterilization as follows: A glass tube is selected large enough to hold the catheters without crowding, and a sheet of filtering paper, rolled in the form of a hollow cylinder, is slipped inside, which clings tight to the glass and absorbs the condensed moisture. The catheters are placed inside the paper, the tips up. The tube is then plugged at both ends with cotton in gauze, the lower plug pushed well up into the tube, which is then placed in the steam. When removed from the steam the paper is taken out and the tube shaken to prevent the catheters sticking together. They can be left in the tube until needed, all in sight. Experiments with anthrax spores, etc., showed that even the smallest catheters were thoroughly sterilized by this method in seventeen, fifteen, twelve, and even in ten minutes. Those that had been oiled and infected several days previously, and not cleaned, were rendered sterile in twenty minutes. He recommends the method as simple, certain, and except for spreading a little in the course of time, the catheters stand frequent sterilization in this manner without injury.—*Chl. f. Chir.*, November 6.

Capacity of the Stomach in Infants. A comprehensive study of this subject in Escherich's pediatric clinic results in the statements: 1. That the stomach of maternally fed infants is smaller than in the artificially fed. 2. That the true capacity of healthy stomachs is less than that of the functionally or anatomically morbid. 3. That the elasticity is greater in small stomachs, and 4, that the true capacity of the stomach is a function depending upon the size of the pylorus. With a narrow pylorus the capacity is large and vice versa. The practical importance of the research lies in the facts established that every healthy infantile stomach can by passive increase in the internal pressure, or from lavages, attain a capacity and retain it for some time, which stimulates dilatation. Large capacity after a lavage does not indicate either atony or ectasia. Repeatedly produced artificial gastroparesis injures the functions of even a healthy stomach musculature, much more where there is motor insufficiency. Consequently loading the infantile stomach should be solicitously avoided, and systematic lavages completely rejected, especially where there are gastroparetic or dilated conditions. The maximal single amount that should be allowed a normally developed infant is: First month, 90 c.cm.; second, 100; third, 110; fourth, 125; fifth, 140; sixth, 160; seventh, 180; eighth, 200; ninth, 225; tenth, 250; eleventh, 275; twelfth, 290.—Moscow Congress, *Wien. klin. Woch.*, November 4.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JANUARY 15, 1898.

THE RENEWAL OF THE ANTIVIVISECTION
AGITATION.

Dr. GALLINGER of New Hampshire on Dec. 15, 1897, gave notice to the United States Senate of his intention to take up at an early day Senate bill 1063, with a view to deciding by a vote whether the bill shall pass the Senate. The bill is the same as S. 1552 of the Fifty-fourth Congress, "for the further prevention of cruelty to animals in the District of Columbia," which was favorably reported from the Committee on the District, May 26, 1896, but which failed to obtain consideration during the short session, or, as stated by Dr. GALLINGER: "Upon solicitation from several senators saying that they were receiving letters from their constituents protesting against the passage of the bill, I allowed it to drift along and did not ask for the consideration of it." It was introduced in the present Congress March 22, 1897, and having been reported favorably from the Committee is now on the Calendar, No. 136. Moreover, the deterring influence of the solicitations from the Senators aforesaid seems to have evaporated, as the bill will not be allowed by its senatorial pilot to drift along any further but will be brought up for consideration and vote.

We have already in our issues of Jan. 23, Feb. 6 and April 3, 1897, called attention to the gross injustice of the proposed legislation in its assumption that the cruelties practiced by the biologists of the District of Columbia, many of them Federal officers and all scientific men of National or more extended distinction, are of such a character as to require Congressional legislation for their restriction. The absurdity of the main argument of the originators of the bill

must be manifest to all who are not zealots in the cause of the Humane Society. This argument calls for legislation to restrict scientific research in the District of Columbia because members of the Humane Society have testified to the horror which filled their souls on observing the atrocities committed in certain of the biologic laboratories of Europe and in thinking of the atrocities which might similarly be committed in the laboratories of the United States. We have called attention also to the assertions on behalf of the bill that no advance has been made in medical knowledge by any work conducted in the laboratories of the biologists, assertions which can be explained only by gross ignorance of the recent history of medical and sanitary progress, or by refractive errors of intelligence which throw all facts bearing on this particular subject out of the focus of mental appreciation. We have also shown, on the other hand, the efforts made by the profession to quiet this agitation of the so-called antivivisectionists. We have shown that not only all the medical associations and societies of the country, but all the scientific and sanitary societies, have memorialized Congress in opposition to the bill, and that even the Department of Agriculture has entered its official protest, citing the benefits to the lower animals themselves in connection with pleuropneumonia, tuberculosis, glanders, anthrax, hog cholera and Texas cattle fever, which could not have been obtained had the Bureau of Animal Industry been handicapped by such restrictive legislation as is proposed by S. 1063.

The AMERICAN MEDICAL ASSOCIATION has done its duty in this connection by placing itself on record as opposed to the bill, but individual members of the ASSOCIATION should not remain passive because resolutions have been adopted in general meeting. Resolutions are all very well in their way, but it is questionable if they will have as telling an effect on a vote of the United States Senate, as an argument by individual members of the ASSOCIATION to individual members of the Senate. Every member of the ASSOCIATION whose opinions have weight should place his opinions where their weight will be felt in a struggle to preserve the right of the medical man to labor in the cause of humanity untrammelled by the restrictive demands of "an over-zealous and intolerant local society" which, according to the Assistant Secretary of Agriculture, "appears incapable of taking a broad and liberal view of the subject."

Medical men in every State of the Union should aid their brethren in the District of Columbia in this fight against restrictive legislation, for if this bill is carried in the United States Senate, its provisions will speedily be brought home to them by the consideration of similar measures in their State legislatures.

Let us have a Department of Public Health!

ETHER AND CHLOROFORM.

In the *British Medical Journal* of Nov. 20, 1897, there appears an interesting paper on the comparative action of the principal anesthetics, ether and chloroform in particular, which was read before the section on anatomy and physiology at the late meeting of the British Medical Association by its president, Dr. AUGUSTUS D. WALLER. It is noteworthy in that it gives the results of experimental studies by a prominent physiologist, whose conclusions have, therefore, a certain authority and it was deemed of sufficient importance to form the subject of a leading article in the same issue of the *British Medical Journal*.

Dr. WALLER's method of experimentation was to test the direct action of the anesthetic on the excitability of the nerve, taking freshly prepared nerves and submitting them to electrical excitation while enclosed in a chamber filled with the vapors of the different anesthetics, the effects being shown by a photographically recording galvanometer. By this method he tested the effects of the vapors of ether, chloroform, nitrous oxid, carbon dioxid, ethyl bromid and other anesthetics upon the nerve and found the results in striking agreement generally with their otherwise observed effects. Thus, ethyl bromid was evanescent but irritating, ethyl iodid produced lingering after-effects, and chloroform and ether powerfully anesthetized the nerve as shown by its galvanometric reaction, the formerly permanently and completely the latter temporarily. It is in regard to these last two agents, which are so extensively employed as anesthetics, that he specially directed the investigation and deduced the practical conclusions.

The chief question at issue in the researches of the Hydrabad commission on chloroform was whether this agent caused death through the heart or the respiration, and the latter view is that maintained by the Edinburgh school, which still advocates by preference chloroform as an anesthetic. It matters practically very little how death occurs, if it does occur, and the real question is what can be done to prevent it. Dr. WALLER's experiments show that both ether and chloroform have a paralyzant action on the highest form of tissue, nervous substance; the former temporarily, the latter permanently. The most important results of his study are summed up by him as follows:

1. Using ether and chloroform at an indefinite but high degree of concentration (about 40 per cent. and 10 per cent. respectively), the nerve has nearly always been anesthetized (= temporarily immobilized) by ether, killed (= finally immobilized) by chloroform.

2. Using ether and chloroform at various definite degrees of concentration (5 to 40 per cent. of the former, 1 to 5 per cent. of the latter) *the action of chloroform has been seven times that of ether.*

3. The action of mixtures of ether and chloroform (seven parts of ether to one of chloroform) is cumu-

lative, the sum of the action of the two constituents.

4. Carbon dioxid *per se* does not increase, but rather diminishes the prolonged anesthetic effect of chloroform.

It will be readily seen that the above conclusions have very important practical bearings, and it is the discussion of these that forms the most important part of Dr. WALLER's communication. If chloroform is seven times stronger than ether in its anesthetizing effect, the quantity of it required is necessarily small and the margin between the proper amount and excess is consequently diminished, thus creating a serious possibility of accidents, quite apart from any specially lethal qualities it may possess. Dr. WALLER criticises the statistics of deaths from chloroform and points out how far they may have been affected by unconscious prepossessions. The fact that the results of the administration have been so generally favorable that it requires the collection of thousands of cases to furnish any appreciable comparative ratios of mortality aids in this error; it is impossible for some with only a fortunate experience to appreciate the real possibilities of danger. Another fact vitiating the statistics is that only a portion of the chloroform fatalities are ever reported and Dr. WALLER, judging from personal knowledge, is inclined evidently to believe that the unreported cases considerably outnumber the reported ones. In Great Britain where chloroform is, more than in America, the commonly used anesthetic, this is very possibly true, and it should be borne in mind in estimating the value of such statistics. That this should vitiate hospital statistics, as he states it does, is less comprehensible and certainly less excusable.

The fourth of the conclusions reached is a rather striking one, and is perhaps liable to misconstruction as regards its practical bearings. If CO₂ is an anesthetic itself and yet an agent capable of aiding the recovery of the nerves from the effects of chloroform, it might be understood that the dangers on the side of the respiration in chloroform anesthesia are non-existent, or at least overrated. Dr. WALLER takes pains to counteract this error, the danger from impeded respiration in chloroform anesthesia is not from the accumulation of carbon dioxid, but from the accumulation and stagnation of chloroform vapor in the lungs. It is possible, he holds, that some mixture of CO₂ may be beneficial in the outset of chloroform administration, and this may be one of the factors in the success of its use in the hands of its adherents, but he expressly says that he does not recommend the administration of carbon dioxid with chloroform, or yet the administration of chloroform alone, and while he says that he is not "altogether adverse to its use," it is evident that the occasions for its employment are in his opinion very limited in number. It is in minor surgery especially that he deprecates its use, and he

states the case forcibly in the following two propositions, which he calls "the chloroform dilemma."

"If chloroform is dangerous under all circumstances, it may not be employed in minor surgery. Death in this class of cases is therefore unjustifiable, and should be considered as a criminal offence. If chloroform is dangerous only when unskilfully administered, then again death by chloroform is unjustifiable, and ought to be considered as a criminal offence."

While this dilemma might be better stated, its logic is certainly worthy of consideration; it leaves very little chance for escape from uncomfortable associations with any accident from the use of chloroform. Undoubtedly the greater ease and convenience of anesthesia with this agent will still ensure its use in many cases, but Dr. WALLER's authority will probably have much weight and influence in diminishing the popularity it still enjoys.

The conclusion to be deduced from the investigation is that it is hardly necessary to seek for special dangers on the side of the heart or the respiration in anesthesia, as nearly all anesthetics are direct paralytics of nerve tissue, and the risk is not so much in the special organ they affect as in their strength as neurotic poisons. The one exception appears to be nitrous oxid, and we may possibly assume, with KEMP in another paper in the same issue of the *British Medical Journal*, that it acts in some way on the highest nerve center, the cerebral cortex. Whether it is as absolutely safe as is claimed is possibly open to question, though there is little doubt that it is comparatively safer than some other agents. For lengthy operations ether, with all its disadvantages, still seems to be the safest and therefore the preferable anesthetic. The study also emphasizes the necessity of the utmost care in the administration of chloroform, when that seems necessary, of avoiding the slightest possibility of carrying the dose above the danger point, which may be assumed to be not far above the optimum anesthetic quantity. The strength of the agent and the consequent small amount required leave a correspondingly narrow margin of safety in this case. The stronger the agent the greater the caution, altogether aside from any local action it may be supposed to have on special organs.

DIABETIC COMA.

PROUT's words that "Diabetic patients constantly live on the brink of a precipice," are especially applicable to the most dreaded of all the complications of diabetes, namely, the coma characteristic of that disease.

In a recent lecture THOMAS B. FUTCHER¹ reviews the etiology, symptoms and treatment of diabetic coma. True diabetic coma was, it will be remembered, first accurately described in 1874 by KUSSMAUL. The

frequency of the complication is shown in the collection of fatal cases by STEPHEN MACKENZIE from the London Hospital, in that all the cases under twenty-five, with one exception, died of coma. Of 400 cases studied by FRERICH'S 250 died, and coma was the cause of death in 150 instances. Of the 39 cases treated in the Johns Hopkins Hospital 15 died, and in 12 death was produced by coma.

Young people, particularly children, are more liable to die of coma than are older patients.

SAUNDBY ranks constipation very high as a predisposing cause, as it diminishes elimination and affords time for fermentative processes that may produce toxic substances. In some cases coma has come on after nervous shock and exposure to cold.

Of the many theories devised as regards the exciting cause of diabetic coma it is necessary at this time to refer only to those which attribute the coma to the presence of either acetone, diacetic acid or β -oxybutyric acid. Now these three substances are very closely related, as shown by their chemie composition and reactions. The detection of acetone in the urine of patients with diabetic coma first led observers to believe that this was the cause of the coma, a view now no longer held because acetone can be given to animals in large quantities without causing intoxication. Acetone also occurs in the urine in many other diseases, especially in severe cachexia, as well as in certain acute infectious diseases.

The appearance of acetone in the urine in diabetes should put the physician on his guard, as its presence is often succeeded by that of diacetic acid and β -oxybutyric acid.

In 1874 RUBSTEIN² demonstrated that the substance discovered by GERHARDT² in 1865, and which gives a Burgundy red color with ferric chlorid, was diacetic acid. Now it was for some time believed that this acid resulted from the oxidation of sugar, and MINKOWSKI² tried to show that the intensity of the ferric chlorid reaction and the amount of sugar in the urine ran parallel, but that sugar is not necessary to the production of diacetic acid is shown in various ways, especially well by the fact that this substance has been repeatedly demonstrated in the urine of fevers, carcinoma, and other diseases without glycosuria. The present opinion is that diacetic acid and acetone are products of albuminous decomposition. In the majority of instances of diabetic coma diacetic acid appears in the urine previous to and during the attack, but KUSSMAUL² and FRERICH'S² have shown that it does not possess any poisonous properties, because ten to twenty grams of the acid can be given without any grave symptoms.

In 1884 STADELMANN, KUSSMAUL and MINKOWSKI showed that the urine of patients with diabetic coma contains considerable quantities of β -oxybutyric acid.

¹ New York Medical Journal, Dec. 18, 1897.

² Fletcher, loc. cit.

This acid is now believed by most observers to be the exciting cause of diabetic coma. It results from decomposition of the body albumins, and many believe that it is the first stage in the formation of diacetic acid. The amount of β -oxybutyric acid eliminated daily may be as much as 20 gms. Its occurrence in the urine in diabetes is of the gravest moment, as it is permanent and has a constant tendency to increase. VON NOORDEN³ shows that this symptom is of the gravest prognostic significance: in most cases after a few days or weeks, diabetic coma ensues and the case passes on to a fatal ending. Hence it may be concluded that diabetic coma is caused by an acid intoxication, due to certain products of decomposition of the body albumins, viz.: β -oxybutyric acid, and possibly also diacetic acid.

The premonitory symptoms of diabetic coma vary. It may begin with maniacal excitement, or more commonly abdominal pain or headache; the pulse is sometimes rapid. At times suddenly, but occasionally after headache and indefinite symptoms resembling alcoholic intoxication for a few hours or days the patient becomes somnolent, and more or less rapidly falls into deep coma. He now lies quietly with at most but slight clonic twitchings; pupils dilated; the eyes may be open, or the lids are slowly raised and lowered. The pulse is small and rather rapid; the temperature at first elevated, later sinks far below normal. The respiration is marked by deep, long-drawn inspiration, succeeded by short expiration. In spite of full aeration of the lungs a gradually increasing cyanosis arises, due apparently to obstruction in the peripheral circulation. The breath may have a fruity odor from the exhalation of acetone. In this condition the patient remains for from twenty to forty-eight hours, rarely longer, and then death follows.

FRERICHS classifies cases of diabetic coma into three groups:

1. Those in which the attack begins suddenly, usually after exertion, and terminates fatally after a few hours.

2. Those in which the duration is longer, the attack being preceded by various symptoms, among others great distress and dyspnea, a condition called by KUSSMAUL "air hunger." The attack may last for from one to five days.

3. Those in which the attack begins without dyspnea or anxiety but preceded by headache, signs of intoxication, disordered gait and gradual onset of the coma. These cases were believed to be due to the action of the poison on the nervous system. The symptoms closely resemble alcoholic intoxication.

The prognosis is grave. There are only three or four cases reported in which recovery has taken place. Prevention is therefore the primary indication in the treatment. All predisposing causes such as constipa-

tion, fatigue, nervous shock and cold should be avoided. VON NOORDEN says that in the prodromal stage when this is recognized, a change of diet, no matter what this may have been, often exercises a beneficial influence. A large amount of alcohol in small doses is necessary. Constipation should be relieved by mild laxatives. Large doses of alkalies have been recommended, e. g., six or eight drachms of bicarbonate of soda per day, according to the theory that the condition is one of acid intoxication.

When the coma has actually set in our present remedies are helpless. Transfusion of blood, inhalation of oxygen, injection of weak solutions of phosphates and chlorids of sodium into the veins, and of a 3 per cent. solution of sodium carbonate have all been used. Intravenous injection of the last solution was successful in only one case of seventeen collected by CHADBOURNE⁴, temporary improvement being obtained in seven. A very common method of treatment at the present time is the subcutaneous and intravenous injection of quantities of normal saline solution at frequent intervals. VON NOORDEN recommends this method highly, and it would seem to be a rational one. In ten of the twelve cases in which coma developed in the Johns Hopkins Hospital this treatment was used, and in two of the cases the patients were restored to consciousness so that they would have been capable of making a will. Subsequently both cases terminated fatally. In three other cases the pulse was improved and the respiration rendered much less labored. Subcutaneous and intravenous injection of salt solution seems to give the best results yet obtained in diabetic coma. In addition injection of camphor and ether may be advised, because they are indicated by one symptom seldom absent in diabetic coma, namely, weakness of the heart.

HEALTH AND LONGEVITY.

The influence of various occupations upon health and longevity is the subject of an interesting investigation just completed by an officer of the Registrar-General's department of the British government. A vast collection of figures and comparative tables have just been issued as a public document, and although at first glance the array of statistics seems formidably dull, some of the deductions from them are instructive and of the widest interest. First and foremost comes overwhelming proof that the work or occupation of some sort, is the greatest promoter of longevity. It is almost alone in England of all civilized countries that this fact can be brought out clearly in public statistics, for it is only in England that the leisure class, so called, is sufficiently large for the comparison to be made. The disparity between the mortality of "occupied" and of "unoccupied" males is very great in favor of the workers, though the data do not

³ Twentieth Century Practice of Medicine, vol. II, p. 95.

⁴ Quoted by Fletcher, loc. cit.

allow the naming of any precise percentage when certain necessary allowances have been made.

The influence of profession upon health and mortality, it is pointed out, begins to be strongly manifested at about the age of 25 years and continues until 65 years. Of course, the employments usually regarded as dangerous figure prominently, file-making taking a bad pre-eminence. The publican class (saloon-keepers) comes next. Innkeepers themselves die more rapidly than their servants, alcoholism and diseases of the liver being the chief causes. The mortality figures of public-house keepers show seven times and of their servants four times more rapid death rate than for the general average of occupied males. It is curious, however, that the death rate for these two classes is highest in the industrial districts of England and lowest in London. Brewers and butchers rank next among important occupations on the high mortality list. They are respectively two and one-half and two and one-fourth times the standard. Chimney-sweeps, dock laborers, coachmen and cabmen are all on the wrong side of the mortality average. At the other extreme are most of the liberal professions, and the clergy enjoy the enviable distinction of passing the greatest number of years in this vale of tears.

Locality seems to have a startling effect upon the mortality records, although this cause is shown to be much more apparent than real. Taking England as a whole, it is shown that 100,000 males born are reduced to 75,149 at the end of the fifth year, while 100,000 females will number 78,324 at the end of the same period. But in certain selected, so-called healthy districts of England and Wales, this reduction is not accomplished until after twenty-nine years in the case of males and twenty-seven years in the case of females. The contrast is even greater in the case of a single city. Thus, in the township of Manchester, which includes only the well-populated section of the city, 100,000 males are reduced to 62,326 in five years and 100,000 females to 66,623 in the same time. But in the healthy districts of Manchester this reduction is not accomplished until the age of 50 among males and the age of 48 among females. Whence it is fair to conclude that the general manner of life and condition of poverty or comfort are much more important factors in the problem of life than mere locality.

THE JOURNAL AND THE ASSOCIATION.

The JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION began its new year with an increased number of pages, and proposes to continue to furnish the same amount of reading pages throughout the year, thus putting it a safe distance ahead of all its American contemporaries.

A new press has been purchased and is now in oper-

ation. The vast amount of MSS. now in the office awaiting publication will, we trust, be reached much earlier, although the members must be aware that it is a manifest impossibility to make use of all the valuable material that comes in to the office, even with the increased number of pages.

The growth of the ASSOCIATION during the past year has not been exceeded by its growth in any previous year, and all that is now needed to maintain it in a healthy condition is, that the members shall once more come to the front, look at their JOURNAL critically, compare it with similar publications, and induce their friends, not already members, to join the great ASSOCIATION. There is no reason why the AMERICAN MEDICAL ASSOCIATION should fail to occupy the same relation to the whole profession that the British Medical Association does to that of Great Britain, where every physician in good standing with his fellows, is, or is supposed to be, a member of the British Medical Association.

As for the JOURNAL, its work in the past speaks for itself, and its growth in the future will depend upon the support and encouragement received from the members of the ASSOCIATION, subscribers and contributors. At no time has its prospects seemed brighter; at no time did it seem to meet more closely the views of its founders. That it is capable of still further improvement, no one doubts, as the moment it ceases to improve, then will it begin to decay.

Not only is the JOURNAL useful to the ASSOCIATION and its important members, but it has a still far-reaching influence beyond that noticed, because at no time has it been more widely quoted at home and abroad by other medical journals than at the present time. The higher average medical education of the present date is having its influence on papers read at the ASSOCIATION meetings; much better work has been done in its Sections, and altogether the retrospective view is pleasant. The increase of reading pages will not only give room for more original matter, but will probably increase the amount of space for Society Proceedings—a very important department of the JOURNAL of which it is impossible to over-estimate the value. Important discoveries and the results of individual research are usually presented first to the local society, although the proceedings are necessarily reported in smaller type, as even the capacious columns of the JOURNAL with its sixty pages of reading matter, exclusive of the advertising pages, can not afford space for everything in pica. The reader must himself to some extent, also separate the wheat from the chaff, but it is interesting to remember, for instance, that the two communications which seemed to attract great attention at Moscow, "MURPHY'S suture of the arteries," and "FRANK'S absorbable coupler," were both presented at a meeting of the Illinois State Medical Society, and reported in the JOURNAL,

June 12, 1897, some time before the meeting of the Congress. "DOYEN'S drain," which was also presented in Society reports, and numerous other instances, crowd upon the memory, of the important achievements of the vanguard of science modestly chronicled in "Society Proceedings" without even a distinction of a separate place in the index, long before the medical world in general awakes to a realization of their value.

In the last year an important historic work, never before translated into English, has been placed at the disposal of American surgeons through the columns of the JOURNAL, without extra cost, and it is therefore with some satisfaction that we reflect on the achievements of the past year, and venture to express the hope that at the close of the year 1898 we shall be able to show even more substantial progress.

To this end we again urge that the members once more take up the aggressive and use their utmost endeavors to make the ASSOCIATION and its JOURNAL a fitting and worthy representative for all that is good for the American medical profession. The membership should be brought up to 10,000 before the Denver Meeting. Great strides have been made toward that end, but let us not relax our efforts.

THE DEATH OF MR. ERNEST HART.

The death of Mr. ERNEST HART, the editor of the *British Medical Journal*, comes with a shock to his many friends in America, most of whom had already learned that he was in feeble health. They sympathized with him in his recent illness and operation, but from the reports published they had been led to believe that he was fairly convalescent.

His death leaves a gap in the ranks of medical journalism which can never be filled. He had an instinctive delicacy of judgment, made few mistakes and popularized the *Journal* as no man preceding him had been able to do, and at the same time made it one of the financial successes of the age. He had learned the art of being aggressive without offending, and the *Journal* under his management has been right in its advocacy of all those reforms in which the whole profession is interested.

As a writer he was forceful, accurate and aggressive. As a man he was unassuming, polite and agreeable. As a physician he was well informed, and in certain lines in advance of his time. He will be greatly missed, for his place in medical literature was peculiarly his own.

CORRESPONDENCE.

Foreign Medical Training for Recent Graduates.

VIENNA, AUSTRIA, Dec. 20, 1897.

To the Editor:—"Foreign Medical Training for Recent Graduates" is the title of a late editorial article in the JOURNAL, and as it is a subject of most vital interest to many young men who belong to this class, I propose to discuss the question briefly in this letter. I do this the more readily from the fact

that many of my friends, who are aware of the fact that I have spent some years abroad, are in the habit of writing to me for advice as to where they had better put in a few months' time in brushing up on the practical points of their profession. I am prompted further in writing this letter, by the fact that I meet here in Vienna, every day, young physicians from the United States, full of energy and wide awake, who are working with an untiring will, but who, from the fact that they are ignorant of the German language and do not propose to stay here until they master the same, are, if not wasting their time, certainly not spending it in a profitable manner.

Let me suppose the case of a young man who has had a few years of general practice, or perhaps has only just graduated. The field that he occupies, or the one that he proposes to occupy, is one where he must play the rôle of the general practitioner in its widest sense.

To keep abreast of the times, he feels the necessity of further instruction, especially in the more practical matters that pertain to his profession. But in looking over his environments, two obstacles present themselves at the very outset. His means are limited and he can only spend a few months away from his field of labor. Where shall he put this time in, at home or abroad? Most decidedly at home, unless however there is a large element of fraud and humbug in his make-up, and he is seeking a very little knowledge and a good deal of buncombe.

Our post graduate schools at home were organized for just such men as he is, and they teach, in the main, just what he most needs to know. A couple of six weeks' courses at one of the best of these will be of more benefit to him than many months spent in a foreign country, where he has first to learn the language before he can profit by what he sees or hears.

Twenty odd years ago, when I first came to Vienna, the condition of things was entirely different. There was no post-graduate instruction to be gotten in the United States at that time, nor, in fact, anywhere else outside of the Austrian capital. In fact, two decades ago this was the acknowledged Mecca, to which all medical pilgrims turned their footsteps who were in search of a higher and more practical medical education.

Some years ago, after leaving here, I went to Guy's Hospital in London, and giving the late Dr. Reese my card asked the privilege of attending his lectures for a time. His reply was: "Yes, Doctor, you are perfectly welcome to attend my lectures, but if you have been taught clinical medicine by Jaksch and Nothnagel at Vienna, you will find anything in that line to be gotten here in London very thin." And thin I found it.

I am glad to say, however, that the number of young physicians from America who are coming to Vienna is gradually diminishing, and we have not more than half as many here now as there were twenty years ago. I believe though that part of this falling off in numbers is due to the fact that more Americans go to Berlin for instruction than in former years.

The private instruction given here is done by the ordinary professors and privat docents. In several branches this class of instructors is far inferior to those of a decade and a half ago. For instance, Bandl, who taught us in gynecology, and Ultzmann in the diseases of the genito-urinary organs in the male, are both dead, while Jaksch, Pawlik and Chiari have been called to fill professorships in the German University at Prague, and their places, in my opinion, have not been filled by men of equal merit as teachers.

Who should come to Germany, in which I include Austria, to pursue their post graduate studies in medicine, and what are some of the advantages to be obtained here? It is nonsense to come here unless you have some knowledge of the German language or intend to stay here long enough to acquire the same. An ordinary traveling knowledge of the language will be of but little benefit to you. You must know

medical German, and that requires a good deal of time and study, as their technical terms are not like ours and the French, derived from the Greek and Latin, but are mostly strictly German in their origin. It will take from three to six months' diligent study to be able to thoroughly understand what you hear. If, however, you are not too far advanced in years and have a sufficient amount of money and time at your disposal, the benefits of a course of study abroad are certainly, not to be ignored, for besides what you know of medicine proper, the acquisition of the knowledge of a foreign language is no small factor in the make-up of an all-around educated man, which every physician should strive to be.

Supposing you understand German, or intend to stay in Germany until you acquire such a knowledge, what are the subjects that are better taught here than at home? First comes internal medicine. Not because the subject is better understood or more skilfully taught than by our best teachers, but because the clinical material is much more abundant here and can be much better utilized for clinical purposes, and the numbers of those to be taught are much fewer in proportion to material available. If one takes Professor Nothnagel and his first assistant, you have thus access to a large number of patients whom you can personally examine, make your own diagnosis, and have it corrected or criticized by your teacher; hear many of these cases discussed fully by one of the best teachers in Europe and follow them to the dead-house, if they die, and observe all the morbid changes that an autopsy reveals. There may be just as good courses as these at home, but I have not been able to avail myself of them, for I have not been able to find them. In the post-graduate courses I have taken in America the teaching of internal medicine has been extremely disappointing, partly on account of its being simply didactic in character, no material being available to give it a true clinical worth.

Again, in the line of obstetrics, you take Professor Schauta's course and that of his first assistant, and these will enable you to watch the course of a large number of natural labors, and you can be called at any hour of the day or night to witness any operative cases that may occur. When we consider that three or four thousand women are delivered annually in this service you can form some idea of the rich field of observation that it gives. Besides this you can examine a large number of women in the last weeks of pregnancy, measure their pelvis, and determine the position and presentation of the child before labor begins.

Where, I ask, would you be able to get advantages like these in the United States? The larger number of Americans here are studying some special subjects, as the eye, ear, nose, throat and the like, and the merits of Vienna as compared with other places for studying these subjects I can not judge, though I find that many get discouraged after remaining here for a short time and return to London or New York. Many of these men who are preparing themselves to play the rôle of specialists are youths just out of college. Few of them seem to be studying that which should be the ground work of a thorough medical education, viz., internal medicine.

For one who understands German, and especially if he has had a few years' practice, the best place to put in a couple of months in Europe is at Berlin, taking in the "Ferien Curs für Ärzte," which begins early in the Autumn and lasts six weeks.

Still, as I said in the beginning, such a course can be gotten in our own country at a much less expense and, taken as a whole, just as good. The exception to this is that the course in gynecology, given by Martin, is better than can be gotten in America, and I am certain that his brilliancy as an operator is not excelled, if equaled, anywhere or by anyone.

A large number of our young men in the profession are surgery mad, scalpel crazy and see nothing in any case that is not associated with the spilling of blood, the tying of arteries,

the closing of abdominal wounds and the application of the model antiseptic dressing. To such I would say, do not come to Europe at all, for I can assure you that you can do much better in America. Here, in Vienna especially, operations seem to be done principally for the benefit of the ten or a dozen assistants who surround the patient.

Then again the teaching is not so good as one can get in New York or Chicago, and the operating is certainly in no way superior. Especially will you find both the medical and surgical gynecology disappointing as compared with what one can see at home if he will follow the work of our best men.

Many of the teachers here in the Vienna school seem to have achieved their positions through some other consideration than their natural ability to teach, as in the case of Billoth, who was one of the most scientific surgeons of this century, but never was a good teacher.

Hence, of late years, when I am in Europe I go to Paris for my surgery; not that it is better done there than here in Vienna, but because the French professor in the school of medicine in Paris is generally a born teacher, explains every step of his operation and allows you, if possible, to see what is done. Then again American physicians are treated courteously in France, while in Germany, if you are not a Senn, a Murphy or some other man of equal eminence you are not likely to get any civilities that you do not pay for; in fact, they seem inclined to put us all down as the graduates of a Buchanan school or some other quack institution.

W. S. CALDWELL, M.D.

Medical Treatment of Appendicitis.

ONEIDA, N. Y., Jan 10, 1898.

To the Editor:—Much has been written of late years on the surgical treatment of appendicitis, but very little on the medical treatment. In a practice of nearly forty years I have had my share of cases, ranging from five to twenty yearly, and thus far have had no case that I have found it necessary to operate more than to aspirate in case of abscess. I have had only one death, a boy 15 years of age, who was hurt while playing at school, and this case, in my opinion, died from lack of good nursing.

My treatment can be given in brief. Although adopted more than thirty-five years ago, I have never witnessed another line of treatment that has caused me to change my own. Unfortunately, many physicians are not correct in their diagnosis, and frequently call peritonitis (especially if pelvic) appendicitis. It is true that the symptoms are in part alike. Both diseases are usually ushered in with a chill followed with fever and abnormal temperature, and my treatment is alike, or nearly so, in both diseases.

If called in the first stage, and there is much pain existing, I give a hypodermic of morphia and atropia, usually $\frac{1}{4}$ grain of the former and $\frac{1}{150}$ of the latter. Ice-bags filled with chopped ice are applied over the seat of pain, and possibly followed after twenty-four or forty-eight hours with poultices, preferably of yeast and charcoal with a good quantity of nitrate of potassium added. The medical treatment consists of commencing at once with tinct. of aconite to control the fever and reduce inflammation, in $\frac{1}{4}$ minim doses repeated every two hours, and $\frac{1}{120}$ grain of corrosive chlorid of mercury every hour, with a teaspoonful of olive- or castor-oil every two or three hours.

I have had cases where I have commenced with 15 to 20 grains of calomel, followed by the above treatment. In some very few cases an abscess has formed in the iliac region which I have aspirated, and then use compression. I have had cases where the abscess broke into the colon and the patient made a good recovery. About a year ago I was visiting in a city some seventy-five miles west of Chicago, and I was told that only a short time before, a man of that city was seriously sick with what was called appendicitis, and a celebrated surgeon of Chi-

cago was called and advised operation at once. This the family would not consent to, and in the evening an old lady came in and recommended giving the patient all he could drink of a tea made of timothy grass seed, and a huge poultice of the seed applied to abdomen. This was done and in less than twelve hours the man was better, and rapidly recovered. I tried the above in a case of a lady a few months ago, but feeling that it was unsafe to depend entirely upon this, I gave my usual treatment and she made an uneventful recovery.

H. W. CARPENTER, M.D.

The Antiseptic Versus the Antitoxin Treatment of Diphtheria.

PHILADELPHIA, PA., Jan. 10, 1898.

To the Editor:—I am not informed whether it is your custom to admit to your columns criticisms of papers appearing therein, but upon reading the paper of Dr. Braymer in the issue of November 27, I am tempted to test the facts in that direction. The point which the paper attempts to cover: "Is, or Is Not Antitoxin the Best Treatment Offered for the Cure of Diphtheria," is one that we supposed had been definitely settled through exhaustive clinical experience, covering a period of time sufficient, it would seem, to justify an affirmative answer in the minds of the most captious. On the contrary, like Banquo's ghost, the subject will not down, and following the usual experience in medical investigation, need we expect it to be set at rest for a century to come? Parallel cases may be cited to prove the likelihood of this prophecy; note the school of anti vaccinationists which flourishes in our own day. Indeed, we find that there is hardly a proposition advanced in any school, no matter how probable, but finds its opponents for a large number of years to come. With the results of clinical theories, however, if the antitoxin treatment can be so called at this time, this communication is not intended to deal, but more particularly with the handling of those theories.

Dr. B. in his second paragraph states: "I have had very limited experience with the remedy, but as yet can not feel that it is worthy of the *advertising* [italics are ours] it has received at the hands of the profession."

In a list of some seventy-four cases, covering a period of years, the Doctor recounts six cases treated with antitoxin. The mortality during the first period under potassium chlorate, iron and calomel treatment, was in thirty-six cases, seven, or 22.22 per cent. During the second period, under antiseptics, there were thirty-two cases with *nil* mortality; and during the third period six cases with two deaths, 33.3 per cent. This would apparently make a strong showing for the antiseptic treatment were it not for the important qualifying elements of character of epidemic, class of cases, etc. The importance of this is well stated in another portion of the paper: "All who have met with many cases of diphtheria know how different the fatality is." "You also know that there is the factor of varying vitality manifesting itself in different individuals." Continuing the Doctor says: "I believe all will agree with me that diphtheria is primarily a local disease, (!) then we ask the question, why not treat it as you would any other like condition, why not treat it successfully by antiseptic?" Why not, indeed? The bite of a rattlesnake, if such can be called a disease, is primarily local, but how long does it remain so? The same might be said for anthrax and tetanus, syphilis, gonorrhoea, and in fact almost all contagious diseases.

In my student days it was the habit of an esteemed professor of surgery to give the class a literal and concise method of treatment for all surgical cases. "Take away the cause and put the part at rest." If this advice could be promptly followed in all cases, the practice of medicine and surgery would be a very simple affair.

If I may be allowed I will quote once more from the Doctor's paper and then conclude: "If antitoxin does any good at all it is only to counteract the effect of the absorbed toxin of the disease." "And those (cases) that have been of several days standing without treatment are admittedly not so much benefited by antitoxin, *perhaps* [italics mine] not more so than by any other rational treatment. Then again the use of antitoxin causes great pain and fright, especially in small children, and this alone might be a cause of death."

There are a few conclusions that I would draw from the reading of the paper. 1. That the Doctor greatly errs in ascribing to the profession generally, or individually, a lack of sincerity in the use of the antitoxin, or an intention to advance the interests of manufacturing houses in the advocacy of its use. 2. That after more insincerity is displayed in ill directed opposition to a remedy or the publication of incomplete collections of cases bearing on their face ample evidence of lack of careful analysis and detailed history.

W. H. BURR, M.D.

A Case of Puerperal Eclampsia (Ante Laborem) With Recovery.

PARK CITY, UTAH, Jan. 8, 1898.

To the Editor:—As there is a good deal of uncertainty in regard to the exact pathology and treatment of puerperal eclampsia, it would possibly throw more light on the management of this dreaded disease if the physicians reported every case in their practice and the line of treatment pursued; especially does this seem important when it is remembered that according to statistics the mortality is 40.5 per cent. if the convulsions set in before the time of labor and about 29 per cent. during labor.

Oct. 23, 1897, I was called on to prescribe for Mrs. S., age 22; pregnant about thirty-seven to thirty-eight weeks; primipara. She was troubled some with vomiting and complained of being very nervous and restless so that she could sleep but very little during the night; had quite a severe pain in the stomach and a good deal of headache. The urine was examined and found normal.

Anodynes were prescribed to quiet restlessness and also lithia water as a precaution, although no kidney lesions could be found. Her husband neglected to obtain the lithia water.

November 1, about 9 o'clock, P.M., I was sent for. Mrs. S. was in convulsions. On my arrival she had just passed out of the first convulsion and was snoring heavily. In about twenty minutes she had another severe one. A hypodermic injection of gr. $\frac{1}{4}$ morph. and gr. 1-150 atropin soon controlled it. There were no uterine contractions. A brisk cathartic was given.

She had during the night seven severe convulsions. She bit her tongue quite badly. The pulse at times went up to 122 per minute. The convulsions were held somewhat in check with morphin and atropin, and Norwood's tincture of veratrum viride. I bled her once by opening the median basilic vein of the right arm drawing about a quart of blood; this seemed to check the convulsions for a couple of hours.

As the convulsions toward morning increased in frequency, at 8 o'clock I decided to bring on labor. Under partial chloroform anesthesia, the cervix was gradually dilated by means of the Barnes bags and the fingers. At half past nine she was delivered of a dead baby. The placenta was removed after twenty minutes and the uterus contracted well. She had one convulsion during the manual dilatation of the cervix. About five hours after delivery she had another severe convulsion; this was the last, making in all nine convulsive attacks. She was unconscious to external surroundings and had no recollection of what had taken place from the first convulsive seizure and until about a day and a half after delivery.

During the puerperium the thermometer registered only

once half a degree above normal. She was given lithia water and the bowels kept open every day. The wounds on the tongue were washed with antiseptics several times a day. The vagina was syringed three times a day with bichlorid of mercury solution. She made a splendid recovery.

E. VIKO, M.D.

"A New Method of Inviting Sleep."

NORTHAMPTON, MASS., Jan. 3, 1898.

To the Editor:—I hope a large number of the readers of the JOURNAL will refer to the September 25 issue and examine the article on "A New Method of Inviting Sleep" and express their opinion of the principle therein contained.

Thinking obstructs sleep. Draw away from the centers of thought power to carry on muscular effort as there described, an equilibrium is established and the normal conditions of sleep exist.

It is not necessary to put in practice this method in order to pass judgment upon its claim as a scientific principle.

Will the many medical men interested in reducing our practical work to the normal basis give us through the JOURNAL an estimate of this method?

I should personally be greatly pleased to receive through the mails any opinion at variance or in consonance with my own.

Respectfully, J. B. LEARNED, M.D.

One Way to Prevent Abuse of Medical Charity.

CHICAGO EYE, EAR, NOSE AND THROAT COLLEGE.

CHICAGO, ILL., Dec. 14, 1897.

To the Editor:—In the *N. Y. Medical Record* of November 27, is given a copy of a circular letter recently issued by the New York Cancer Hospital, which is sent to the family physician of all patients applying to their clinics for free treatment, in which inquiry is made as to the ability of the patient to pay. In all cases wherein it is learned that the patient is able to pay further clinical services are denied.

The same idea was adopted by the Chicago Eye, Ear, Nose and Throat College several months earlier as may be seen by appended copy of letter issued at the time of its organization, to every doctor in Cook County.

Would it not be just to place the credit for the idea where it belongs, and give us the precedence of having adopted a practical means for discouraging clinical pauperism?

Yours truly, J. R. HOFFMAN, M.D., Sec.

CHICAGO EYE, EAR, NOSE AND THROAT COLLEGE,

CHICAGO, ILL., March 26, 1897.

Dr. _____

Dear Doctor:

M_____ has applied to us for treatment as a charity patient, and has given your name as having been the former medical attendant. We have been led to suspect that this patient is not entirely unable to pay, and hence is not entitled to free treatment, which it is our aim to extend only to the worthy poor.

Do you consider the above mentioned patient as being one entitled to free treatment?— We will consider this communication as strictly confidential. If not a worthy poor patient, will decline to extend further free treatment, and refer same to you.

Yours very truly,

CHICAGO EYE, EAR, NOSE AND THROAT COLLEGE.

Confidential remarks.

Medical Law in Indiana.

CHICAGO, Jan. 10, 1898.

To the Editor:—Will you kindly give through the JOURNAL the new or present medical law in Indiana, and oblige

A SUBSCRIBER.

New Indiana Law as to Practice of Medicine.—After the

taking effect of the act approved March 8, 1897, any person desiring to begin the practice of medicine, surgery or obstetrics in Indiana, must procure from the State Board of Medical Registration and Examination a certificate that he is entitled to a license therefor. To do this, he must submit his diploma, and make affidavit of the time and under what circumstances he received it. Besides, the affidavits of two freeholders, resident in his county, stating that he is the person named in the diploma application for a certificate, must accompany the application. The fee is \$6. All persons already practicing, are given ninety days to obtain a certificate, by presenting to the board the license possessed by them at the time of the passage of the law, with an affidavit that they are the legal possessors of the same, and the persons mentioned therein. The fee they must pay is \$1. The board's certificate, when presented to the county clerk of the proper county, entitles the holder to a license to practice medicine, surgery and obstetrics in Indiana, on payment of 50 cents for issuing and recording it. If an applicant presents a diploma from a medical college which is not recognized as maintaining a sufficiently high grade or standard of medical education as defined and fixed in the records of the board, he is given the privilege of being examined as to his qualifications, in such manner as the board may provide, and if he fails once, may try again within twelve months. Fee, \$25. An appeal also lies, on giving bond for costs, to the circuit or superior court, to require the board to show cause why he should not be permitted to practice. Change of residence from one county to another requires a new license, to be obtained by filing the old one with the county clerk of the latter county. The board is to be composed of five members, appointed by the Governor from reputable physicians of the State, graduates of a college of medicine of good repute. Each of the four schools or systems of medicine having the largest numerical representation in the State shall be represented on it, but not more than three members shall be of one political party. No professor or teacher in a medical college is eligible. Meetings shall be held on the second Tuesday in January, April, July and October of each year, at least. Schedules of the requirements made of applicants for examination, and of medical colleges, must be kept, and, after 1897, no change shall be made therein after the month of January of each year or affect students theretofore matriculated. The board is not to discriminate for or against any school or system of medicine, or prescribe which shall be taught in State institutions. But it shall have power to make all necessary rules and regulations for reciprocal recognition of certificates issued by other States, and to prevent unjust and arbitrary exclusiveness by other States of Indiana graduates who have filled its requirements. It may refuse to grant a certificate to any person guilty of felony or gross immorality, or addicted to the liquor or drug habit to such a degree as to render him unfit to practice medicine or surgery, and may, after notice, hearing and judgment of a "guilty" thereon by the judge of the circuit court, revoke a certificate for like cause, subject to appeal. Midwives of ten years' practice are also allowed to procure certificates, within ninety days, on affidavits. Others must present diplomas from a recognized obstetric school, or pass an examination. Nothing in the act is to prevent rendering services in emergencies or administration of family remedies. Neither is it to apply to any commissioned officer of the United States army, navy or marine-hospital service in the discharge of his duties; nor to any physician or surgeon, who is legally qualified to practice in the State or Territory in which he resides, when in actual consultation with a legal practitioner of Indiana; nor to any physician or surgeon residing on the border of a neighboring State and duly authorized to practice under the laws thereof, whose practice extends into Indiana, provided, he shall not open an office or appoint a place to meet patients or receive calls in Indiana. It is further provided that this act shall not be construed to prevent medical students from practicing medicine and surgery under the immediate supervision of a licensed physician; nor shall it apply to legally qualified dentists when engaged in the exclusive practice of dentistry; nor to any optician who shall hereafter engage in the practice of optometry; nor to non- itinerant opticians engaged in the practice of optometry in Indiana at the time and prior to the passage of this act. To open an office for such purpose or to announce to the public in any way a readiness to practice medicine in any county in Indiana, or to prescribe for, or to give surgical assistance to those suffering from disease, injury or deformity, shall be to engage in the practice of medicine within the meaning of this act. Any person who shall practice medicine, surgery or obstetrics in Indiana, without having a license duly issued as provided therefor, shall be deemed guilty of a misdemeanor, and on conviction thereof shall be fined not less than \$25 nor more than \$200.

"One Dr. Eastman."

INDIANAPOLIS, IND., Jan. 6, 1898.

To the Editor:—In the issue of the JOURNAL for December 25, Dr. M. Price of Philadelphia, discussing extra-uterine pregnancy, observes: "My case at term, reported some five years ago, was in the tenth month of gestation and in the amniotic sac. The mother and child are today both living and well, the child a beautiful little girl. This case is reported in 'Greig Smith's system of Abdominal Surgery' as operated by one Dr. Eastman. No one of the name is known to belong to the profession of Philadelphia. This goes to illustrate the worthless character of the statistics of even eminent authority. This case is stated by Smith to be the only one in America where mother and child both lived." At the onset we will disclaim any intention to champion the accuracy of Greig Smith's statistics, since indeed a typographic error in the volume referred to made it appear that "Eastman of Philadelphia" (instead of Eastman of Indianapolis) had operated in tubal pregnancy, saving mother and child. But because of this single error, shall Dr. M. Price conclude recklessly, "my operation has been credited to one Dr. Eastman?" We think not. In the statistic assailed the words "Eastman of Philadelphia," were marked by an obelisk which it was intended should refer attention to a foot-note at the bottom of the page, giving the *American Journal of Obstetrics* of October, 1888, as the source of the operation of "one Eastman." It is passing strange that Dr. M. Price did not remark this date, 1888. Why did he not take up his *American Journal of Obstetrics* and learn to whom Greig Smith alluded? Dr. Price says, "my case was reported some five years ago." According to his own statement, therefore, not earlier than 1892. The case of Dr. Joseph Eastman of Indianapolis, is recounted in nearly all of the standard text-books dealing with such matter, which have appeared since July 10, 1887, the date of his operation (Playfair, Greig Smith, Pozzi, Keating and Coe, etc.), and has been discussed in French, German and English magazines. In all instances except one (Greig Smith's work) this particular operation has been ascribed to Dr. Joseph Eastman of Indianapolis. Dr. Price in including the case among his own, indeed "illustrates the worthless character of the statistics of even eminent authority." Many of the works (notably that of Greig Smith, 1889) and magazine articles referred to were published several years before the confessed date of Dr. Price's operation.

We assume, with no thought to commentate concerning the scope of Dr. Price's reading, that none of these have come to his notice. It remains to be added that the method employed in the two operations controverted was essentially different. Dr. Price left the amniotic sac stitched to the wound and placenta *in situ*; whereas Dr. Eastman removed the entire sac, clamped the uterine end of the tube and the broad ligament, cut away the portion which contained the ovum and quilted the stump with iron-dyed silk.

JOSEPH RILUS EASTMAN, M.D.

License in Germany; American and European Medical Colleges.

CHICAGO, ILL., Jan. 10, 1898.

To the Editor:—I am again forced to reply to Dr. Becker of Toledo, and this time on a different subject. I must therefore apologize for using two headings for this communication.

As far as the laws regulating the practice of medicine in Germany are concerned, I am done and shall waste no more time with them.

But Dr. Becker accuses me of underrating the value of American medical colleges, particularly of Johns Hopkins or Harvard. Now any careful reader, familiar with the most rudimentary principles of English composition, will see that I

never expressed my opinion, but that I was stating what legal value the diplomas of an American medical school has before the German licensing board in Germany.

My opinion puts Johns Hopkins and Harvard even above the average German university. To me Osler is second to none, and Kelly far outshines, as a surgeon, men of even the caliber of a Bergmann, which gentleman, for instance, although one of the German surgeons, has won for himself the distinction of carefully neglecting asepsis.

And now to the address of Dr. Becker a few well-meant advices: 1. "Polk's Directory" is a poor weapon to fight with, as it is not a scientific publication. 2. It is not considered good journalism to indulge in personalities. Stick to the subject in consideration, Doctor, and do not argue about a man's shoes and clothing, or his nose; babies only argue in this way. 3. Barnes Medical College is an excellent institution, and has men on the faculty who are far more able to teach than many professors in Zurich. So, for instance, Charles H. Hughes is well known throughout this country and Europe as an authority in neurology, Pinckney French as a most successful scientific and aseptic surgeon, Carpenter as a clinical lecturer of whom it has been justly said, "he is a clinical lecturer even if without clinical material."

Perhaps Dr. Becker will be surprised to learn that his diploma from Zurich is absolutely valueless in several States of the Union, as Kentucky, Tennessee, and that in order to practice medicine there he would have first to produce an American diploma. If he ever wished to move there, I would earnestly advise him to enter the graduating class of Barnes Medical College. I believe the faculty of that institution would give him three years credit for his diploma, and I am satisfied that he could yet learn something in that successful college, which in its six years existence had to abandon quarters for more spacious ones, larger than those assigned to the medical department of the University of Zurich.

G. A. BLECH, M.D.

A Simple Method of Preventing the Clouding of Mirrors.

MILWAUKEE, WIS., 1897.

To the Editor:—The *Medical Press and Circular* recently called attention to an ingenious, effective, and at the same time very simple device for preventing the clouding of mirrors used in the work of laryngologists and dentists.

The method was introduced by George Wallis, L. D. S., dental surgeon to the London Throat and Ear Hospital at a recent meeting of the staff.

It consists merely of smearing a thin layer of ordinary soap, soft but not moist, over the surface of the mirror, and afterward polishing the latter with a dry cloth. The effect of this procedure is that however much the mirror may be breathed upon, its reflecting surface remains perfectly clear and bright. When one takes into consideration the extreme simplicity of the procedure and the bothersome difficulties sometimes encountered in preventing the clouding of mirrors used in laryngology and dentistry, the value of this ready method can not be overestimated. It has proved very satisfactory to me, and as I have not yet seen it mentioned in the American journals, I take this opportunity of calling the attention of the profession to it.

Yours very truly,

GILBERT E. SEAMAN, M.D.

Birth Mark?

WAUKEGAN, ILL., Jan. 6, 1898.

To the Editor: J. F. M. is 13 years old, and is usually in good health. He is myopic and his eyes are elongated antero-posteriorly. The pupils are exactly alike, elliptical in shape, the pointed portion of the pupil being downward like a

snake's eye. The mother thinks the boy is "marked." While she was pregnant, a few months before his birth, she was frightened by a snake and for weeks afterward she fancied she could see that snake's eyes.

Is the boy "marked"?

Respectfully,

J. M. G. CARTER, M.D.

PUBLIC HEALTH.

Reappearance of the Plague in Bombay.—Bombay dispatches of January 6 give the plague returns for the preceding forty-eight hours, 142 new cases and 105 deaths. There is a general exodus of the population and a suspension of business threatened.

Appointments.—Mr. Nathan Straus, of sterilized-milk fame, has been appointed president of the Board of Health of the City of New York, *vice* Mr. Wilson. Dr. Wm. T. Jenkins and Dr. John B. Cosby have been appointed health commissioners. Dr. Jenkins brings to his new office the experience gained as former health officer of the port.

Health in Michigan.—Reports to the State Board of Health for December give the ten diseases most prevalent as: Rheumatism, neuralgia, bronchitis, influenza, tonsillitis, diarrhea, inflammation of kidney, pneumonia, pleuritis and erysipelas. Consumption was reported at 178 places; diphtheria, 85; typhoid fever, 84; scarlet fever, 72; measles, 56, and whooping cough at 20 places, there being an increase in consumption, diphtheria, scarlet fever, measles and whooping cough and a decrease in typhoid fever, as compared to the report for November.

The Pilgrimage to Mecca was accomplished this year in remarkably good sanitary conditions. Notwithstanding the 200,000 pilgrims gathered during the four days of the festival, not a single case of the bubonic plague nor of cholera was discovered, thanks to the action of the Anglo-Indian government in prohibiting the departure of pilgrims from the infected Indian ports. But twenty days after the close of the festival, the bubonic plague appeared at Djeddah, the nearest port to Mecca. Prompt measures in accordance with the program adopted by the International Conference at Venice, and the extreme heat, stamped out the epidemic by July, with a record of only fifty-eight deaths. It was undoubtedly due to the contraband trade in goods and transportation between India and Arabia, which will continue to be a menace to the health of Europe until suppressed by concerted action.—*Janus*, October.

Good Health at Pittsburg, Pa.—The annual report of the Board of Health of Pittsburg, for 1896 has recently been issued. The report shows the number of deaths to have been 4,907 or 17.3 per thousand of population (estimated at 282,500). The death rate is lower than at any time since 1886; and considerably lower than in 1891, when it was 23.6. The number of infants born during the year was 7,462, being an increase of 709 over the previous year. The births exceeded the deaths by 2,555. The Board makes bacteriologic tests in cases of suspected diphtheria and furnishes antitoxin, produced by the bacteriologist of the department, Dr. Matson, free of charge for physicians of Pittsburg, and adjacent districts. The report shows that 1,216 doses of antitoxin serum were distributed last year, 220 of these going outside of Pittsburg. Mr. Matson is of the opinion that the fatal cases of diphtheria were reduced one-half by the use of antitoxin last year. The disposal of garbage is satisfactory. The city has as yet no municipal hospital for contagious diseases. The health officers, as in duty bound, repeat the recommendation made in former years that one be established without delay. Let them not cease the necessary reiteration until they get it, for get it they will and must.

Neglect of Vaccination in Northern London.—The *Lancet* says that if Islington is again overtaken by one of those great epidemics of smallpox which have affected it more than once in the last twenty-seven years it will not be the fault of its indefatigable medical officer of health, Mr. Alfred E. Harris. Mr. Harris has just published some statistics which may well alarm that public of this great parish. These figures show that there has been a steady increase in the neglect of vaccination during the last twelve years, so that, whereas in 1885 of 9,683 children born, only 8 per cent. were finally unaccounted for, in 1896 of 9,752 children born no less than 22.4 per cent. are unaccounted for. Such wholesale violation of law is doubtless the fault of the guardians more than of the inhabitants. It is nothing short of a scandal that a board of guardians should override the wisdom of the legislature. The vestry of Islington has very properly protested against the guardians being in this matter the sanitary authority. One thing, however, is clear, that if at the approaching election of guardians this question is not put into the very front of those on which the election will turn the inhabitants will then become responsible for the unprotected state of the children, and for general treason to the teachings of science and of common observation.

Sanitary Care of Canned Foods.—Dr. T. Brown, at the Sanitary Congress at Leeds, avowed himself to be a strong advocate of legislation in the matter of canned foods. In regard to tinned fruits Dr. Brown said he had not heard of any case which had ended fatally. He had, however, made numerous analyses showing that in cans in which lead was used in tinning or soldering, the former metal was found in the fruits and syrup. How long foods hermetically sealed would keep was not definitely known. Having had canned foods, including meats, soups, rabbits, giblets, and oysters from twenty to thirty years, he had found that the tins, though rusty outside, were perfectly good inside. The meats were sound, though not as fresh and tempting to the eye as recently prepared samples. In canned fruits, however, the effect of age was that the acids of the fruits dissolved, by chemic and galvanic action, the plating and solder with disastrous consequences. To safeguard the public health, Dr. Brown recommended the government to forbid tinned foods in which tin used for plating contained more than 1 per cent. of lead or more than 10 per cent. in solder, the same law in fact which had been in force in Germany since 1889.

Relations between Medical Examiners and local Boards of Health.—Dr. Hurd, medical examiner at Newburyport, Mass., refers to a case of sudden death regarding the disposition of which there happened to arise a clashing of authority, and the courts were called upon to arbitrate between the two authorities. Dr. Hurd thus writes to the *Boston Medical and Surgical Journal*, for December 16, regarding the discrepancy and its settlement: "This is the case where the Board of Health of Ipswich, thinking their rights interfered with by the removal of this body to Newburyport (that is, from one town to an adjoining town) without their permission, and believing that the law defining the functions of boards of health gives such boards authority over medical examiners in such cases, who must apply to these boards for consent before they can legally remove bodies out of one town into another—this board, I say, appealed to Justice Sayward, of Ipswich, who sustained the view of the board, and fined the undertaker who took the body from Grape Island to Newburyport, \$10 and costs. An appeal was made to the superior court, and the case was *nolle prosequi* by District Attorney White, so that, according to this judgment, medical examiners are not amenable to boards of health in the discharge of their duties within the limits of their districts."

Sanitary Regulations as to the Plague in South Eastern India.—Plague is increasing in India. It is feared that it will break

out somewhere in an epidemic form, and the necessity for active intervention occur. A recent telegram from Madras, reported: "Three fresh cases, one has terminated fatally." "The appearance of the plague," says the *British Medical Journal*, "at Madras is interesting epidemiologically, as we have no previous record of plague there. The cases, as far as we can learn, are important cases merely and in accordance with what we now know of plague we should not anticipate an outbreak there in an epidemic form. A telegram from Jullundur, a town in the Punjab, states that twenty-three deaths have occurred there 'from what is believed to be the plague.' Jullundur is directly in the track northward from Bombay of the course the plague has followed previously. In the hospitals at Poonah, 294 cases of the plague are being treated, and the physicians are attending 115 cases in Bombay hospitals. Whilst Poonah is relaxing her efforts by as far as possible annulling the severe segregation rules enforced when the plague first appeared, Bombay is strengthening hers by imposing quarantine upon new arrivals. The period of detention will extend to six days, and accommodation will be provided for about 6,000 people. With the quarantine arrangements surveillance tickets are issued, whereby well-known people can avoid the quarantine on the understanding that they present themselves for examination on the third and sixth days after arrival. As well-nigh a third of the cases occurring in Bombay are imported, these regulations have shown excellent results. The inspection is rigid, and no person passed out has been known to have become subsequently attacked."

The Ship Island Quarantine.—The resolution recently introduced in the United States Senate by Senator Walthall of Mississippi, instructing the Committee on Health and Quarantine to investigate by what right the Quarantine Station, which was removed some years ago from Ship Island, off the Mississippi coast to Chandeleur Island, had been returned to Ship Island, will receive general indorsement in this section. The resolution further instructed the committee to report, by bill or otherwise, the proper measure for removing the station from Ship Island to some other point in the Gulf remote from the mainland. This resolution undoubtedly voices the wishes of the people of the whole tier of States bordering on the Gulf of Mexico. Ship Island is not a fit place for a quarantine station, for the reason that it is too close to the mainland, and is in daily communication with all the towns along the coast, because a large amount of traffic goes on constantly between the ships taking in cargo at the island and the mainland; and lastly, because fishermen and pleasure-seekers are frequent visitors to the island. A quarantine so situated can not but be dangerous to the health of the watering places along the Gulf Coast, and through them to the neighboring cities of Mobile and New Orleans. There is a very grave suspicion that the recent visitation of yellow fever came through Ship Island. At any rate, it first made its appearance at Ocean Springs, which is but twelve miles from the island. No matter how strongly the Government officials may claim that the quarantine plant at Ship Island is not dangerous to the health of the people residing on the mainland, it should nevertheless be removed, as it is unwise to take any chances in matters affecting the public health. Moreover, the people of the coast towns firmly believe that the Ship Island Quarantine Station is a menace to them, and its perpetuation would materially retard their prosperity. It was a great error to have re-established it on Ship Island after it had once been removed from there, and Congress should promptly provide for its transfer to some more isolated place. Chandeleur Island is not a pleasant place of residence for the quarantine officials, but that is not to be considered in comparison with the safety of the entire Gulf coast. Editorial in *New Orleans Picayune*, Dec. 16, 1897.

Inadequate Organization of Boards of Health Disclosed by the Yellow Fever Epidemic.—In proportion as the organization of sanitary boards is made complete and satisfactory, the panicky feeling in

our epidemic-struck communities declines. The weak points in State and local boards are emphasized by such outbreaks of yellow fever as have visited our Gulf Coast, this year. A writer in the *New Orleans Medical and Surgical Journal*, November, alludes to the panic that has affected the Louisiana parish in which he lives, adding "and as is usual where there has been extreme fright, there has been almost complete absence of common sense in the exercise of powers conferred by law. Every neighborhood is suspicious of all other places; each municipality has enacted laws to protect itself without due regard to the rights of others, and in most instances very much more stringent than the situation demands. I suppose there are today, in the State of Louisiana alone, over five hundred local boards of health, each a law unto itself, and without the least attempt at uniformity or co-operation for securing protection against the yellow fever. The Board of Health of Louisiana, as at present created, serves an excellent purpose as far as the City of New Orleans is concerned, but in an emergency of this kind is of but little benefit to the State at large. I believe if a general law was passed, excessive and unwise quarantines, such as New Orleans and the entire State are suffering from now, would be impossible in the future. My suggestion is that the State Board of Health be composed, as at present, with the same number of members from the city of New Orleans, and also have a number from each parish in the State and one from each town of certain population. The Board should have its domicile at the State Capitol, and should hold annual meetings for discussing such questions as might come up of interest to the public health; in fact this board should take charge of the public health of the State in its broadest sense. Each member from a parish or town ought to be the regularly appointed health officer for that parish or town and, acting under rules adopted by the State Board, should take charge of all quarantines during an outbreak of any epidemic, or infectious disease. He should at all times look after the health of his parish or town, register births, deaths, etc. If some law of this kind could be passed and all laws repealed giving police juries and corporations power to form themselves into boards of health, I believe the end of shotgun quarantine would be at hand, while the public health would be more thoroughly protected than it is now; the embargo on freight, as far as this State is concerned, would not be necessary. Confidence among the people in a board of health of this kind, I believe, would soon be acquired, and no one would wish to go back to the primitive methods of complete isolation to prevent the spread of disease."—James Kilbourne, Clinton, La.

BOOK NOTICES.

Clinical Text Book of Surgical Diagnosis and Treatment. By J. W. MacDONALD, M.D. Professor of the Practice of Surgery and Clinical Surgery in Hamline University, Minneapolis. 328 illustrations, pp. 798. Philadelphia: W. P. Saunders. From W. T. Keener, Agt. 52 Randolph Street, Chicago. Price in cloth, \$5.00, half morocco, \$6.00.

This book might, with advantage, be compressed into two-thirds its size as it is verbose in its expressions, and the art of condensation, so far as the author is concerned, is a lost art.

The author's ideas are a little foggy in respect to tumors page 561, "Fibro-myomata and Fibromata." "Between the simple gelatinoid polypus and the true fibroma may be found mixed tumors of all grades, from those containing the slightest trace of fibrous material to those difficult to differentiate from the true fibroid: the gravity of the case varies in proportion to the amount of fibrous substance, because that is very vascular, and the chief danger of removal lies in the hemorrhage."

Page 563: "Adenomata and cysts are to be regarded as modifications of mucous polypi, with similar symptoms and treatment, though the former may take on the characteristics of

carcinoma and the latter do not tend to recur when once their contents are evacuated."

Page 667: "Psammomata are warts found only in the pia mater of the brain and spinal cord."

We notice on page 598, that the old student's lamp is introduced as a means of examining the larynx; in these days of gas and electricity, the student's lamp has not only ceased to shine in most offices but the electric head light has superseded the one here figured.

There are some funny errors in the text. We notice on page 579, in speaking of the deviated septum, he says: "One of the early proposed methods was that of *Adanus*." Adanus we suppose must be the new way of spelling Adams.

There are some errors of statement; for instance, on page 241 the author says: "In the following table I have tried to place, side by side, the diagnostic difference in the three forms of obstruction;" and then under the first heading, "Strangulation by bands," we find that this is confined to "young males." Our personal experience is entirely contrary to this proposition, as we have repeatedly found these bands in young women, especially in cases that had been subject to former operation, and we believe it will be found, by most surgeons, that there is practically no difference in the relative frequency of strangulation by bands in one sex or the other. There are many good points in the work, which concludes with a chapter on the X-ray and surgical diagnosis.

Hugh Wynne, Free Quaker. Sometime Brevet Lieutenant Colonel on the Staff of his Excellency, General Washington. By S. WEIR MITCHELL, M.D., LL.D. (Harvard and Edinburgh.) Two volumes. New York: The Century Company. 1897.

From the days of "Ivanhoe," "Thaddeus of Warsaw," and "Leather Stocking" down to the present time, the historic novel has always been a favorite.

This book should be a favorite with physicians on account of the fact that it was written by one of the guild, so well written indeed that it is destined to take rank with the leading favorites of the past, and it seems at last as if the present generation would have, in the person of Dr. Mitchell, an American novelist worthy of the name.

This story is laid in the times of Washington and inside glimpses are given of early Quaker life in Philadelphia, and the names familiar to us in history are handled as familiar contemporary characters. The work ranks well as a novel and the reader's interest does not flag from beginning to end. Moreover, there is a certain charm in reading a story about which one knows, in a general way, the subsequent history of the principal characters of whom he is reading; and if in addition there is knack in telling the story, interest is all the deeper. "Hugh Wynne" is a book to be read with pleasure by American physicians and laymen alike, and most interesting is the account of life in the Philadelphia prison during the British occupancy of the city. Dr. Mitchell has scored another success.

Ambroise Paré and His Times, 1510-1590. By STEPHEN PAGET. New York and London: G. P. Putnam's Sons; Knickerbocker Press. 1897.

The *fin de siècle* seems to be the age of reminiscences in historic matters, and medicine is feeling the effect of this wave of reminiscence. Last week we chronicled the appearance of two works, John Hunter and William Harvey, and here we record the appearance of a story of Ambroise Paré, newly told in English dress. The life of no surgeon has been more romantic, more full of adventure or of excellent professional work than that of Ambroise Paré, and heretofore there has been but little of it in the English except in scattered volumes, and Mr. Paget has placed the profession in his debt by reaccounting the details of his life.

The volume gives his boyhood and early life and his journeys in diverse places: notes of the journeys in diverse places;

Paris from 1541 to 1572; Paris from 1573 to 1590; opera omnia: some aspects of Paré's life, and Paré's account of the plague.

There are some fine illustrations which the reader will find of interest, especially the frontispiece, which is a reproduction of a portrait in the possession of Mme. La Marquise Le Charon, a descendant of one of Paré's daughters and which was painted when he was 65 years old, with a *fac-simile* of Paré's signature written across it. The other illustrations in the work are reprints from Paré's books, from old prints in the British Museum and from M. Martial's "Ancien Paris."

A System of Medicine by Many Writers. Edited by THOMAS CLIFFORD ALBUTT, Professor of Physic in the University of Cambridge, etc. Pages 1001. New York: The MacMillan Company, 66 Fifth Ave. 1897. Price \$5.

This volume covers some topics which have not been provided for in the preceding volumes and scarcely provided for in the nomenclature. "General diseases of obscure causation," is the rather unscientific title of one of the chapters, under which head is included discussion on acute rheumatism, chronic muscular rheumatism, rheumatoid arthritis, rickets, acromegaly, hypertrophic pulmonary osteoarthropathy, gout, diabetes mellitus, diabetes insipidus, lardaceous diseases, diseases of alimentation and secretion, including general pathology of digestion and secretion, shock and collapse; diseases of the mouth and esophagus, diseases of the stomach, diaphragmatic hernia, abdominal diagnosis from the gynecologic standpoint, enteroptosis, diseases of the peritoneum, diseases of the bowels. There are twenty-three illustrations, a plate and various charts and bibliographic references. The volume is quite up to date in its discussions on the treatment recommended. Drs. Church, Cheadle, Archibald Garrod, Kent Spender, Still, Ralfe, Mr. Bowlby, Sir William Roberts, Drs. Saundby, W. L. Dickinson, Fenwick, Bradford, Cobbett, Rollson, Brunton, Stocker, Allbutt, Dreschfeld, White, Howship Dickinson, Leith, Playfair, Mr. Treves, Drs. Allchin, Eustace Smith, Patrick Manson, Willis and Allingham are the contributors to the volume.

Rubaiyat of Doc Sifers. By JAMES WHITCOMB RILEY. Illustrated by C. M. Relyea. New York: The Century Company. 1897.

This is a poem by James Whitcomb Riley, in which the life of "Doc Sifers," an ideal country doctor, is fully set forth in the dialect of Hoopole Township, Posey County. The Doctor's virtues are set forth in such fashion that one can not but love and esteem the old country practitioner. Riley depicts him, as follows:

"He's jes a child's what Sifers is! And sir I'd ruther see,
That happy, childish face o' his and puore ictimlicity,
Than any shape, er style er plan o' mortals otherwise—
With perfect faith in God and man a-shining in his eyes."

Mr. Riley makes the rustic worshiper of Doc Sifers speak thus of his library.

"Doc's lib'ry—as he calls it—yes, they's ha'f-a-dozen she'vees,
Jam full o' books—I couldn't tell how many—count yourse' ves!
One whole shef's works on medicine! And most the rest's about
First Settlement, and Indians in here—fore we driv 'em out."

Text Book of Materia Medica for Nurses. Compiled by LAVINA L. DOCK, graduate of Bellevue Training School for Nurses. Third Edition, revised and enlarged. New York and London: G. P. Putnam's Sons. 1897.

Much in these days is expected of the trained nurse, and her training includes lectures on surgery and materia medica as well as on the subjects supposed to be within her peculiar province. The contents of the volume are as follows:

Part I. Inorganic materia medica; the alkalies; of alkaline earth; metals; non-metallic elements; inorganic acids; organic acids; the carbon compounds.

Part 2. The organic materia medica; the vegetable kingdom; the animal kingdom; new drugs arranged alphabetically; appendix; index.

Diseases of the Stomach, their Special Pathology, Diagnosis and Treatment, with Sections on Anatomy, Physiology, Analysis of Stomach Contents, Dietetics, Surgery of the Stomach, Etc.: in three parts. By JOHN C. HEMMETER, M.D., PH.D., with many original illustrations, a number of which are in color, and a lithograph frontispiece. Pp. 788. Philadelphia: P. Blakiston, Son & Company. 1897. Price \$6.

The work is divided into three parts, of which part first is devoted to the anatomy and physiology of the digestive organs, methods and technics of diagnosis; Part 2, to the therapy and materia medica of stomach diseases; Part 3, to the gastric clinic.

The work is completely scientific, modern, accurate and creditable. There is one defect in it, however, which must strike the average reader with regret, and that is that the references are, with exceptions, foreign; work done in our own country escapes with scant mention. For example, under the head of foreign bodies in the stomach, a number of cases of hair ball are recorded all from foreign journals, while the one published in this journal (Vol. xxvi, page 199) by Allen, is unnoticed. Notwithstanding this defect, the book is an excellent one and stands fully abreast with the German works on this subject. We commend it. The illustrations are excellent, the paper is good and the publishers have given the work a handsome setting.

NECROLOGY.

JOSEPH O'DWYER, M.D., College of Physicians and Surgeons, N. Y., 1866, one of the visiting physicians of the New York Foundling Hospital, died of tubercular meningitis at his home in New York city, January 7, aged 55 years. Twelve years ago he achieved even international fame by his intubation method of treating laryngeal diphtheria. He was a progressive, enthusiastic physician, in much favor with the profession for his candid and kindly manner.

EDWARD L. DODGE, M.D., N. Y. University Medical College, 1888, died suddenly from blood poisoning following an operation, January 3, aged 39 years. He was born in Springfield, Mass., and practiced in Brooklyn, N. Y. for 12 years. Just before his death he had secured a position on the eligible list of Police Surgeons.

FRANZ HEUEL, M.D., N. Y. Medical College (now extinct), 1857, who belonged to the German revolutionary army of 1848, and emigrated to this country after its defeat, died in New York city, January 4. He was once attached to the Health Department, and also served as a Dispensary physician. He leaves two sons who are also members of the profession.

SAMUEL HENDERSON MCILROY, M.D., Long Island College Hospital, 1864, was a war veteran, member of the Grand Army of the Republic, a Fellow of the N. Y. State Medical and American Medical Association, and belonged to many fraternal bodies. He was born, June 21, 1839, in Scotland, Pennsylvania, not far from the Gettysburg battle field. He was a popular, well-read physician, and up to within a year of his death, when his health failed, he enjoyed a lucrative practice. He died January 5 and left a widow with three children.

ERNEST HART, Editor of the *British Medical Journal*. Mr. Hart was the author of a number of works on sanitation, etc., and had been conspicuous for his devotion to social and sanitary progress in London. He established a society for the abatement of smoke, and instituted cheap concerts for the poor. As chairman of the Parliamentary Bills Committee of the British Medical Association he took an active part in promoting a better organization of the medical departments of the British army and navy. Among sanitary investigations he especially inquired into the various epidemics due to the pollution of milk and devised a series of regulations for safeguarding the milk supply of towns. After investigating the conditions of the Irish peasantry in Galway, Donegal, and Mayo he

published in the *Fortnightly Review* proposals for favoring the creation of a peasant proprietary and for reclaiming waste lands. These were adopted by the government.

WILLIAM SCOTT TREMAINE, M.D., U. S. A., retired, died Sunday Jan. 9. He had been ill for several weeks. He was a native of Charlottetown, Prince Edward Island, where he was born Sept. 13, 1838. He was graduated from the University of Pennsylvania, and entered on the practice of medicine, which he followed until Aug. 7, 1863, when he entered the volunteer service as assistant surgeon of the 24th Massachusetts Infantry, serving until April 12, 1864, when he was honorably mustered out. On May 2 he was commissioned surgeon of the 31st United States Infantry, from which he resigned Sept. 9. He then entered the United States Volunteers as assistant surgeon and on June 4, 1866, was honorably mustered out, having been appointed to a like position in the regular army. This appointment was made Feb. 28, 1866, but he did not accept until June 12, eight days after he was mustered out of the volunteer service. On September 16, he was promoted to the rank of Captain. He served on several stations in the Atlantic division, and then was sent to Ft. Dodge. While there he was taken ill, and for two years was absent on sick-leave. In 1882 he was promoted to surgeon, with the rank of Major, and detailed for active duty at Fort Porter. On Feb. 27, 1891, he was retired owing to disability, after having been on sick-leave for some time. He leaves a widow and six children, Morris Tremaine of New York city, William Tremaine of Chicago, Mrs. H. F. Hall of Jersey City, Mrs. Nairn Walsh and Miss Florence Tremaine of Pittsburg, and Miss Grace Tremaine, who lived with her parents in this city. Dr. Tremaine was one of the founders of the Medical Department of Niagara University, and one of its first professors of surgery. He was a member of the military order of the Loyal Legion, which is composed of commissioned officers of the Civil War, or their eldest sons; of the Masonic Order, of the Buffalo Club and the local medical societies.

Louis Crusius, M.D., Professor of Histology at the Marion-Sims Medical College, January 2, aged 36 years.—L. B. Lindsay, M.D., Cadiz, Kentucky, January 3, aged 71 years.—W. H. Negley, M.D., Dayton, Ohio, January 5.—James Stanton, M.D., San Francisco, Cal., December 28.—Dr. Zaccharin, physician of Czar Alexander III., Moscow, Russia.—John R. Preston, M.D., born February 15, 1809, died in Schuylerville, N. Y., January 2.

NEW INSTRUMENTS.

A NEW PHOROMETER.

BY JOHN O. MCREYNOLDS, B.Sc., M.D.
DALLAS, TEXAS.

In the department of ophthalmology no line of research in recent years has attracted so much attention as that pertaining to the extrinsic muscles of the eye. And in view of this rapidly growing importance of an accurate knowledge of the various anomalies of the ocular muscles, it becomes necessary to employ as aids in diagnosis instruments of the greatest precision and convenient of manipulation. This demand has been met in part by several devices invented for this purpose, but some of the best of these in frequent use have covered only a portion of the field of inquiry. Without offering any extended criticism on the very excellent instruments already introduced, I should like to present to the profession a phorometer, which in my judgment will combine every essential feature that could with reason be desired.

This instrument has been made for me by F. A. Hardy & Co. of Chicago, and their kind co-operation I wish sincerely to acknowledge in this connection.

The construction is roughly outlined in the illustration which accompanies the following brief description of the essential

features of the phorometer. The instrument rests upon a loaded metal base which can be placed upon a table as conveniently as if it were an ordinary lamp. It is supported by a vertical metal rod composed of two pieces, one of which slides within the other, and is provided with a fixation thumb screw, by means of which the height of the instrument can be regulated according to the height of the patient to be examined. Attached to the upper extremity of this supporting rod is a horizontal metal bar, which can be maintained in correct position by means of an endless screw bearing upon a cogged wheel, the position of the bar being determined by a spirit level, with which it is provided. The preservation of this horizontal position is important, because any oblique position would modify the axes of the prisms employed. The horizontal bar is grooved, for the reception of two entirely similar slides which are situated beneath the bar, and along which they can be made to move freely, or can be firmly secured at any point by fixation thumb-screws arranged for this purpose. This feature enables us to regulate the phorometer according to the pupillary distance of the patient. Each slide is also provided with a specially constructed spring clip, which will hold in position a Maddox rod double prisms, colored and stenopeic discs, or various refracting lenses.

But most important of all, each slide carries a cell which can be made to revolve freely within the slide which contains it, or can be fixed in any desired position by a set screw. The advantage of this fact is that the prismatic effect of the cell may be exerted in any direction whatever, and this direction is indicated by the graduated circumference of the slide.

Each cell is composed of two prisms of 15 degrees each, superimposed one upon the other, the two prisms possessing the power of revolving with equal rapidity, but always in exactly opposite directions, the motion being communicated to them by a thumb-screw whose distal end is provided with cogs articulating with the circumferences of the prisms between which it is placed. Since the two prisms always move simultaneously and with equal rapidity and in opposite directions there are two points in each complete revolution of the prisms at which they completely neutralize each other, and these points, which are situated at opposite extremities of a diameter, are marked 0 upon the graduated circumference of the cell.

Now it is evident, that starting at a point at which the two prisms neutralize each other, a revolution through an arc of 90 degrees will cause the bases of the prisms to exactly coincide and their apices to correspond, thus giving a total prismatic effect of 30 degrees, equal to that of the two prisms combined. This point is accordingly marked 30 degrees on the circumference of the cell, and is situated just 90 degrees from the points marked 0 degrees. It is also evident that at 180 degrees from the point just marked 30 degrees there will obtain the identical relations of the prisms to each other, and this point should accordingly be marked 30 degrees. Then the intermediate points in each quadrant between points marked 0 degrees and 30 degrees can be easily determined by calculation or neutralization by prisms of known strength, and thus the graduation of the circumference of the cell is completed. The cell as thus arranged is capable of manifesting in a rectilinear direction a prismatic effect varying by insensible gradations from 0 degrees to 30 degrees. The cell in the other slide is capable of accomplishing the identical result, and hence with the complete phorometer we can secure any amount of prismatic power from 0 degrees to 60 degrees. Not only this, but since each cell is freely movable within the slide which contains it, we can at will determine the direction in which

this prismatic power shall be exerted.

The important feature in the effect of two equal and superimposed prisms revolving in contrary directions within the same cell, is that the image transmitted through them is always deflected in a straight line and not in curves, and that the increments of prismatic power are infinitesimal, so that the maximum impulse to fusion of images is secured.

For the practical application of this instrument to the various forms of heterophoria, the procedure would be briefly as follows:

To test for esophoria and exophoria; so adjust one cell that it will produce a vertical diplopia. Then so adjust the other cell that it shall be neutral, and in such a position that subsequent rotation of its prisms will produce horizontal deflection. Then if the images are in the same vertical line the examination shows orthophoria, and if the images are not in the same vertical line rotate the prisms, producing lateral deviation, until the images pass through the same vertical line and the index

of the instrument will point out the number of degrees of esophoria or exophoria, according to the circumstances of the case.

To test for hyperphoria, right or left, start with the cells in the same positions as above, then rotate the prisms of cell producing lateral deflection until horizontal diplopia is produced, and then rotate prisms of cell producing vertical deviation until the images appear in the same horizontal line, and read off the hyperphoria upon the graduated arc of the cell.

For measuring abduction, start with the same positions as above and rotate prisms of cell causing lateral deflection so that their bases pass inward, and as soon as fusion of images is no longer possible the limit of abduction is reached and can be read from the arc.

For measuring adduction, adjust both cells so that the subsequent rotation of prisms will cause horizontal deflection of images and then rotate the prisms so that their bases turn outward and continue until diplopia develops and then read the degrees from the two cells, and the sum will represent the total power of adduction.

For testing sursum-duction and deorsum-duction, place both cells in neutral position, one of which must have the axes of its prisms horizontal, and then rotate these prisms until the power of fusing the images is lost, and read from the arc the degrees of sursum-duction, or deorsum-duction, as the case may be.

Finally, for any kind of oblique, horizontal or vertical rectilinear deviation leading to diplopia, adjust the neutralized cells so that their prismatic power when exerted shall be in the direction favoring the fusion of images, and when monocular vision follows the phorometer will indicate the strength and position of the prisms which measure the heterotropia. These possibilities are true whether the deviation is due to spasm, or paresis, or paralysis of one or more ocular muscles, provided the extent of the deviation does not exceed 60 degrees, which is the maximum capacity of the instrument described. But if it is desired the strength of the component prisms could be readily increased so as to extend still further the field of investigation.

In conclusion I would say, that with this phorometer we can measure with rapidity and accuracy any form of simple or compound heterophoria and any form of diplopia within the combined power of the prisms employed.

SOCIETY NEWS.

Boston Medical Society.—At a meeting of the Boston Medical Society held on Jan. 1, 1898, the following officers were elected for the ensuing term: Dr. S. Goodman, president; Dr. R. K. Noyes, first vice-president; Dr. F. J. Kelleher, second vice-president; Dr. M. Gerstein, secretary; Dr. V. Bychower, treasurer; Drs. N. M. Goodman, Chas. F. Parker, A. Rovinsky, H. P. Leonard, J. J. Ilanley, B. L. Bernard, directors. The subject for discussion was "Medical Abuses in the Hospitals and Dispensaries, Their Causes and Remedies for the Same." The following took part in the discussion: S. Goodman, F. F. Whittier, N. M. Goodman, F. J. Kelleher, Gustavus Liebman, Ph. Losnowsky and A. Rovinsky. Papers on the subject were read by Drs. R. K. Noyes, Chas. F. Parker, M. Gerstein, the latter dwelling on the abuses in the lying-in-hospital out-patient department.

MISCELLANY.

The Russian Kvas as a Substitute for Beer.—Dr. Karl Frankel has suggested the Russian drink kvas as a substitute for beer, which so many of the members of the congress at Moscow, though tasting it for the first time, found so pleasant and

refreshing. During the hot days at Moscow nothing seemed more palatable than this simple fermented liquor, which is not unlike our own popular root beer. Kvas contains scarcely 0.5 per cent. of alcohol, and most Americans who attended the congress would agree with Dr. Frankel that it would form an excellent substitute for beer during the heated term when the desire to consume a good deal of liquid is almost irresistible. —Correspondent of the *Medical News*.

Can Not Testify to Own Insanity.—For the purpose of avoiding the legal consequences which would naturally follow from joining in the erection of a division fence, the plaintiff, in the case of O'Connell against Beecher, was permitted to testify that in 1883 he fell from a building, and was severely injured. This, the fourth appellate division of the supreme court of New York holds, October, 1897, was competent. But he was further permitted to testify that for eight or nine years thereafter his mind was not right. That this latter testimony was not stricker out, on objection, the court pronounces reversible error, on the ground that the witness was not an expert, and was not competent to give an opinion upon this question. It would establish a dangerous rule, the court goes on to say, to hold that a party to a contract or a transaction is competent to testify that he was not of sound mind at the time of the transaction, or at the date of the contract.

Naval Hospital Corps Proposed.—Secretary Long has sent to the House Naval Committee a draft of a bill "to organize a hospital corps of the United States Navy, to define its duties and regulate its pay." The Secretary says it is understood that the operations of the Army Hospital Corps are satisfactory, and that a similar organization in the Navy can be established and maintained with practically no additional expense. The corps, as proposed, is to consist of twenty pharmacists at \$75 per month and five at \$100; sixty-five hospital stewards at \$60; thirty first-class hospital apprentices at \$24; sixty hospital apprentices at \$18. The proposed naval hospitals are to be located at Portsmouth, N. H.; Chelsea, Mass.; Newport, R. I.; New York City, Philadelphia, Washington, Norfolk, Va.; Pensacola, Fla.; Mare Island, Cal., and Yokohama, Japan. The scheme includes navy yards and flagships.

Suggestive Statistics.—New York, or since the opening of the year, more correctly Borough of Manhattan, New York City, has one ward, the tenth, with a population of 413,000 to the square mile and a voting strength of nearly the unit. The population of the Whitechapel district of London is 393,000 to the square mile. New York consumes daily 25,000,000 more gallons of water than does London; the former city has a birth every nine minutes and a death every ten and a half minutes, while the latter city has a birth every three minutes and a death every five minutes. In London one out of every sixteen inhabitants seeks relief through public charity, while similar aid is sought in New York by one out of each two hundred. London has a police force of 16,000 while New York has to depend upon not quite half that number, but in London the population moves more like a procession than in New York and much more alertness is required in the management of its street traffic, with perhaps a greater respect for the rights of the individual. Still, New York arrogates to itself the finest constabulary of the world. Travelers agree that both these great communities display the racial stoicism of the Teuton even in their crimes, without the leaven of gayety in their sports so apparent in Paris. The struggle for existence in all three of these dense communities has nearly obliterated the Spartan simplicity of the home and has focused their wealth in divers enterprises. The whole three at the present time are trying to refract their accumulations over the diminished areas of a more compact aggregation of living masses. In other words, the moneyless are in a state of siege, with the watchword that the world owes them a living. Sanitation may make life more tolerable, but can scarcely be expected to enter too deeply into moving causes.

Retirement of Dr. Julius Kohl.—At the annual meeting of the Illinois State Board of Health held at Springfield, Ill., Jan. 4, 1898, the following was adopted relative to Dr. Julius Kohl, whose time on the Board had just expired:

WHEREAS, The term of service of Dr. Julius Kohl as member of the Illinois State Board of Health having expired by limitation, we, his late associates, take the occasion of his retiring to express our regard for his ability, professional probity and sterling manliness. Honest, sincere, discreet, fearless in the discharge of every duty, Dr. Kohl won our respect and esteem while with us, and at parting, carries with him our solicitude for his welfare, our best wishes for his happiness.

Hereditary Insanity as a Defense.—In the murder case of State vs. Van Tassel, the defendant's father testified to the insanity of a brother, an uncle of the defendant. Was this single circumstance admissible in evidence? The supreme court of Iowa holds that it was not (October, 1897). It says that when there is evidence of a want of motive, or other evidence furnishing a basis for inquiry as to the insanity of the accused at the time of committing the criminal act, evidence of hereditary insanity may be introduced. But mere proof of insanity in a parent will not be sufficient to constitute a defense if the other evidence negatives the presence of insanity in the accused. Proof of hereditary insanity is admitted as cumulative evidence, and insanity of ancestors is of itself no defense. The reason for this, undoubtedly, continues the court, is that the burden is upon the defendant to establish this defense by a preponderance of the evidence. And proof of an isolated case of insanity in the family, especially that of a remote relative, will not of itself overcome the presumption of sanity.

Intratracheal Medication.—Dr. J. A. Thompson's article in the *JOURNAL* of June 26 has received the compliment of editorial discussion in the London *Lancet* for September 4. The writer in that discussion may be said to be in agreement with the American physician, but has doubts whether or not the localization of treatment along the respiratory tract can be extended beyond dilated bronchi. It may be expected that if a large tuberculous cavity communicates with a bronchus it is possible that a tracheal injection of guaiacol might prove beneficial; but that the drug acts locally on the lung tissue itself, especially at the apices, has by no means been proved. The *Lancet* article also remarks that medicines administered by tracheal injection are not changed by passing through the digestive organs into unknown compounds, and for this reason we can be more certain of their action. "No one would think of treating a tuberculous laryngitis by internal medication alone. There is just as much reason for applying medicines of known beneficial local action directly to the lungs as there is for using them in the larynx." (Quotation from Dr. Thompson.) The weak point of this suggestion is that we can not get at the diseased portions of the lungs as we can at the larynx, but at the same time if guaiacol has a local action on tuberculous deposits, if the injection is well tolerated, inspiratory efforts may carry the drug some little distance into the lung and some of it may be absorbed by the parenchyma of the lung, and so the desired effect be produced. Guaiacol and similar preparations frequently produce ill effects when taken by the mouth, and have to be discontinued: so also various expectorants, such as are used in acute and subacute catarrhal diseases, act injuriously on the stomach and intestine. The name of one class, nauseating expectorants, testifies to the universal recognition of this fact. The diseases most suitable to this form of treatment, according to the writer, are pulmonary tuberculosis, pulmonary syphilis, chronic bronchitis, inflammation of the trachea, asthma and bronchiectasis. Tracheal injections have been most extensively tried in pulmonary tuberculosis and with varying success by different observers. The writer appears to endorse the opinion of the American physician when advocating his method in chronic bronchitis. He believes there is no comparison between the two methods of treatment. The results are so much more rapid and satisfactory by intratracheal medication that no patient who has once been given this treatment is ever willing to continue internal medication. The method will doubtless be given an extended trial, and the experiences of other physicians will be awaited with interest.

Surgery of the Lungs.—The more accurate diagnosis which is now possible with radiography, more general recognition of the tolerance of the lungs and improved technique are leading to more frequent intervention, Tuffier remarked in his address at Moscow on this subject. Most of the 306 operations on record have been performed for gangrene. The immediate result is the disappearance of the putrid expectoration and of the fever. Much depends upon a soft, well-adjusted drain. The following remarkable results have been attained: Thirty-nine recoveries in fifty-five metapneumonic gangrenes; one in four cases of gangrene with ectasia of the bronchi; two recoveries in seven cases of embolism; one in one from a gunshot wound. In forty-nine cases of abscess of the lung, probably mostly encapsulated intralobular suppurating pleuritis, 23 per cent. succumbed to the pneumotomy. Three cases of incipient tuberculous foci were cured, but the operation in cavities was followed by death in thirteen out of twenty-six cases operated. The opened cavities rarely cicatrized and only one or two were improved. Intraparenchymatous injections in tuberculosis also proved ineffectual. No primary neoplasms have yet been operated, but seven cases are on record in which a sarcoma had extended to the wall over the lung and been operated. For these difficult operations he resorts to tracheal insufflation with respiration by pressure through a tamponed canula introduced into the larynx. He rejects puncture in hydatid cysts as unreliable and dangerous, from possible perforation of the bronchi. There are twenty-nine operations for aseptic lesions on record (twenty-two recovered, 75.8 per cent.; and seven died, 24.1 per cent.). This includes traumatic lesions, hernia, neoplasms and tuberculous nodules. Sixty-one operations were performed for hydatid cysts (fifty-five recoveries and six deaths). The remaining 215 were performed for septic lesions (140 recovered, 64.8 per cent.; 75 died, 35.2 per cent.). This includes tuberculous cavities, 36, 16 deaths; abscesses, 49, 12 deaths; bronchiectasia, 45, 13 deaths; foreign bodies, 11, 4 deaths; gangrene, 74, 30 deaths; actinomycosis, 1, no death. Total 306; cured, 217; died, 88. Sapieko stated that he locates adhesions with an exploratory needle connected with a manometer; when the point of the needle projects into an open space the manometer is lowered, while it remains stationary if the needle encounters adhesions. Doyen urges the utmost possible haste in suturing the pleura. He exhibited a laryngeal canula with bulb to produce strong artificial respiration in asphyxia. D'Antona recommends provoking coughing, compressing the sound lung at the same time, which causes the diseased lung to bulge out through the wound and prevents pneumothorax.

Lowell Institute Lectures, 1897.—One of the Lowell lectureships was this year held by Prof. Michael Foster of Cambridge University, who is to consider a subject of unusual interest to our profession. "Some Features of Brain Work" were presented by this well known English physiologist in a course of six lectures, beginning October 18. From the brief summary printed on the tickets, as well as from the success of the opening lecture, it is evident that the physiology of the nervous system in its unity as well as its complexity, as revealed by modern research, is to be sketched by a master hand. Professor Foster requires no introduction to those members of the medical profession who have obtained their medical education within twenty years. In his text-book, published for the first time in 1877, the advanced student and the original investigator found not a collection of isolated and often conflicting statements, but a logical and careful presentation of evidence, with wise suggestions as to the direction in which truth was to be sought in those fields where investigations had yielded only uncertain results. In its successive editions the work has kept pace with the advance of physiology, and its author has shown us how in physiology, as in other sciences, the "solid nucleus of acquired truth year by year grows larger at the expense of its envelope or zone of strife where truth and error mingle in conflict." Professor Foster began his career as a physiologist in 1867, as lecturer on practical physiology in University College, London. In 1869 he was appointed professor in the same institution. In 1870 he became prelector in physiology at Trinity College, Cambridge, and in 1883 was appointed first professor of physiology in the University of Cambridge. Since 1881 he has held the position of secretary of the Royal Society, and in this capacity has exerted a strong influence upon the develop-

ment of science in England. He took a prominent part in the deliberations of the International Congress of 1896, in which it was decided that, beginning with the year 1900, a card catalogue of the scientific literature of the world shall be published under the auspices of the Royal Society, and when this great undertaking shall be inaugurated the result will be largely due to the energy and sagacity of Michael Foster.—*Boston Medical and Surgical Journal*.

Successful Evacuation of Hydatid Cysts of the Liver.—Cheney (*Archives of Pediatrics*, Vol. xiv, No. 11, p. 851) has reported the case of an Italian boy, 7 years old, who came under observation with vague symptoms: Occasional pain in the right side, headache now and then but not constantly, and during the previous week several vomiting spells. His appetite was reported to be fair. He slept well at night and his bowels moved regularly each day, but his mother had noticed a swelling in the right side, about two years before, which had never disappeared, but had rather grown larger. The child appeared healthy, although his body and limbs were moderately emaciated. No icteric hue could be detected about the skin or conjunctiva. The tongue was heavily coated with a yellowish fur. On inspection a swelling was plainly visible in the region of the liver, and on palpation it was found to extend downward as far as the level of the anterior superior iliac spine, and inward to the median line. The swelling was evidently somewhat tender to the touch. Its outline was smooth, not nodular, and its consistence hard throughout most of the extent, but in one part, about three inches below the border of the rib, the swelling was distinctly fluctuating. Running across the right side of the abdomen, just below the border of the ribs, there was appreciable to touch and sight a sulcus or groove, apparently separating the mass below from the liver above. The lower border of the tumor was sharp and distinct, and the examining fingers could easily be inserted beneath it, and it descended on deep inspiration. On percussion there was dullness over the area of swelling directly continuous with the liver-dullness above, but not extending to the lower edge of the tumor as determined by palpation. In a zone about two inches in width over the lowest portion of the tumor the percussion note was tympanitic. The dullness extended to the median line internally and to the axillary line externally. Directly back of the axillary line and posteriorly toward the spine the percussion note was tympanitic, the dullness not extending in that region below the normal liver-dullness. Heart, lungs and urinary secretion were normal. Fluoroscopic examination showed distinctly the upper rounded border of the liver rising and falling with each respiration, but it failed to give any idea of the relation of the parts below the level of the ribs and, therefore, left the character of the tumor in doubt. As a final resort puncture with a hypodermic needle was made at the point where fluctuation had been found, and fluid was obtained which was turbid and looked like thin pus. Under the microscope it showed many pus cells, but no echinococcus hooklets. The diagnosis lay between malignant disease, abscess, or hydatid disease of the liver and sarcoma of the kidney or pyonephrosis. To remove the doubt an abdominal incision was made, when it was at once seen that the tumor involved the substance of the liver. From the superficial appearances it was thought to be an abscess of the liver and this organ was accordingly stitched to the edges of the incision, the wound packed with gauze and the boy put back in bed to await the formation of adhesions before opening the abscess. On incising the tumor three days later, thin turbid fluid escaped, together with numerous transparent glistening cysts the size of grapes. The cavity was washed out and the wall of the mother cyst removed. The latter when distended must have measured between four and six inches in diameter. After its removal the liver still seemed to be too large, so that a long hypodermic needle was passed from the cyst cavity upward into the liver beneath the ribs and with this there was withdrawn perfectly clear transparent fluid. An incision was then made in the track of the needle and another cyst, equally as large as the first, was evacuated of its contents of fluid and daughter cysts. Drainage tubes were inserted, the wound dressed and the boy put back to bed. He recovered slowly but without complication.

Societies.

The following meetings are noted:

Alabama.—Madison County Medical Society, Huntsville, January 3.

Illinois.—Chicago Medical Society, January 12, Chicago. Pathological Society, January 10.

Indiana.—Vigo Medical Society, Terre Haute, January 6.

Iowa.—Clinton County Medical Society, Clinton, January 4.

Michigan.—Academy of Medicine, Kalamazoo, January 4.

Missouri.—Annual meeting of the St. Louis Academy of Medical and Surgical Sciences, January 4.

New York.—Medical Society of the County of New York, New York City, December 27.

Ohio.—Guernsey County Medical Society, Cambridge, January 4; Marion County Medical Society, Marion, January 4.

Texas.—Central Texas Medical Association, Hillsboro, January 11 and 12; Corsicana Medical Society, Corsicana, December 26.

Louisville.

GOVERNOR'S MESSAGE.—The message of the Governor to the assembled legislature contains many valuable suggestions which are of interest to the profession. Among many may be mentioned:

Charitable Institutions.—The report of all the Asylums for Insane shows an average decrease in expenditure per capita of \$11.35, which in the main is due to the reduction of the salaries of many of the officers. The Central Asylum has saved \$10,000 from the appropriation and an ice-plant will be erected which will furnish ice for the institution and by its sale in an adjoining town realize sufficient to pay the running expenses. The Blind Asylum through its excellent management has saved \$17,000, which is being used in the construction of additional buildings providing a hospital for the inmates, and remodeling the old building. The Deaf and Dumb Institute is recommended to have its appropriation increased as it has labored under the disadvantage of want of room. An appropriation is asked for the providing of adequate sewerage at the Central and Eastern Asylums.

Houses of Reform.—It is urged that the appropriation necessary for the erection of this institution be provided at once, and that one additional commissioner be appointed as the Board, as at present constituted, is often evenly divided and much important work thus hindered. The appointment of an additional Commissioner would obviate this.

Board of Health.—Attention is called to the fact that there is no State in the Union in which the appropriation is so small for the purposes of this Board as in Kentucky, and that there is none where the Board renders more efficient service. He concludes his reference to the Board of Health as follows: "The operations of the Board in preventing the spread of yellow fever and the prevention of the shipment of diseased cattle into this State is worthy of especial commendation. By their persistent and intelligent action the advertising quack has been driven from the State, on account of which the people have reason to congratulate themselves."

PROFESSOR LAPLACE, of Philadelphia, was the guest of honor at the meeting of the Medico-Chirurgical Society, held on the evening of the 7th inst., the Society being entertained by Dr. Wm. L. Rodman. Because of the social feature of the evening, there was no essay presented, but in lieu of that Dr. Rodman presented several very interesting and instructive cases, chief among which was the patient a picture of whom is to be found in the "System of Surgery," by Park, of multiple enchondromata. The patient was to be operated on the next day, it being necessary for him to sustain an amputation of the right arm, on account of a sarcoma involving the elbow-joint. The Society was entertained by Prof. Laplace in a discussion of this case. At the conclusion of the meeting the following gentlemen met around the banquet board, at the Pendennis Club: Drs. W. L. Rodman; Ernest Laplace of Philadelphia; Johnson of Bowling Green, Ky.; Carl Weidner, Wm. V. Laws, T. H. Baker, Henry Orendorf, George W. Griffith, Jno. G. Cecil, J. A. Larrabee, M. F. Coomes, W. O. Roberts, H. A. Cottell, W. E. Grant, S. E. Woody, J. W. Irwin, Jos. M. Mathews, Louis Frank, A. M. Cartledge, J. N. Bloom, W. H. Wathen, Fouché Samuel, T. S. Bullock, Ap Morgan Vance, H. H. Grant, J. M. Ray, J. E. Hays, Wm. Cheatham, T. H. Stucky, Frank Wilson, Jno. Williams, T. C. Evans, S. G. Dabney, Henry E. Tuley, and Dr. Wm. Bailey, who acted as toast-master. The following toasts were responded to: "The Medico-Chirurgical Society" by Dr. John A. Larrabee; "The Medico-Chirurgical College," Prof. Laplace; "The Clinical Society" by Dr. J. N. Bloom; "The Surgical Society" by Dr. Lewis S. McMurtry; "The Commonwealth and the State Board of Health" by Jos. M. Mathews, and "Reminiscences" by Dr. H. A. Cottell.

DR. LONG.—It is announced that the Governor has accepted the resignation of Dr. J. P. Huff, for some time Superintendent of the Feeble Minded Institute and has appointed in his stead Dr. Jno. L. Long, formerly of this city, but of late First Assistant Physician at the Central Kentucky Asylum for the Insane. There will be a promotion among the assistant physicians and the position of third assistant has been offered Dr. Louiss Bergman, and has been accepted. This is the first opportunity that the woman in medicine has had for showing what she is worth in the minds of the profession of the State and the community.

Philadelphia.

DEATH RATE.—The total number of deaths in Philadelphia during last year was 22,735; the mortality ratio being 18.72 per 1,000 living; the smallest death rate in this city since 1879, when the ratio was 17.37. The highest ratio during the last ten years was 22.25, in 1892.

PREVALENT DISEASES IN 1897.—During 1897 the deaths from some of the principal causes were assigned in the Registrar's Report as follows: Consumption of the lungs, 2,388; inflammation of the lungs, 2,723; diseases of the heart, 1,297; cholera infantum, 852; marasmus, 765; inanition, 523; convulsions, 670; teething, 90; apoplexy, 798; cancer, 688; tumor, 118; typhoid fever, 401; uremia, 343; diphtheria, 1,231, and membranous croup, 243. In addition to the above there were 22 deaths from sunstroke, 143 from suicide and 814 from old age.

DIPHTHERIA.—There has been, during the last three or four months, an epidemic of diphtheria of moderate severity, affecting principally Germantown, which is one of the choice resident wards of the city, and which being on elevated ground and well drained is usually regarded as one of the healthiest. All the usual measures and some extraordinary precautions were taken. Nevertheless, the cases continued to increase until it was found advisable to close the neighboring schools temporarily. An attempt was made by the physicians of the health board to make a systematic inspection of the throats of all the pupils before admitting them to the class rooms, each morning, but after a brief experience it was found to be impracticable and was abandoned. Indeed, some of the pupils positively declined to permit the physical examination of their throats to be made and when they were refused admission to the schoolroom the parents, in one or two instances, sent them back with threats of legal proceedings, including injunctions and mandamuses, which complicated matters so much that the directors concluded to send all the children home and to have the infected schools thoroughly cleaned. The number of deaths from diphtheria in 1896 was 862; 1897 it was 1,231 exclusive the 243 deaths returned as membranous croup. It is probable that the antitoxin treatment has been used more extensively in this epidemic than in any which preceded it and from the experience obtained in such a large series of cases it is hoped that valuable deductions will soon be made in contributions to our medical journals and medical societies. The marked increase of the fatal cases of diphtheria over the preceding year of 369 deaths does not warrant an unfavorable verdict in the absence of other data, although if it had been the other way it might have been claimed by enthusiastic advocates as a triumph for antitoxin (*vide* report of the New York Board of Health for 1895). The mortality rate under this treatment will begin later when the entire number of patients treated by this agent has been made known and its value may then be more definitely settled. There was also an increase of 221 in the number of deaths from scarlatina last year over that of the preceding year.

HYGIENIC SCHOOL REGULATIONS.—The Committee on Hygiene of the Board of Education considered favorably the suggestions contained in a communication from the City Board of Health and recommended their adoption: 1. That individual drinking cups be provided for each of the pupils. 2. That passing of pencils from one pupil to another be prohibited. 3. That schools in infected districts be scrubbed once a week and floors and walls washed with carbolic acid solution. 4. That children having symptoms of illness be promptly sent home to remain until well. 5. That wall decorations of plants and shrubbery be not allowed to remain on the walls of class rooms longer than between sweepings.

COLLEGE OF PHYSICIANS.—At the annual election January 5, Dr. John Ashhurst, Jr., was elected president of the College; Dr. William W. Keen, vice-president and Dr. Thomas R. Neil-

son, secretary. Dr. M. B. Hartzell read a paper entitled "Infectious Multiple Gangrene of the Skin, Report of a Case with Illustrations." Dr. John B. Deaver read a communication on "The Necessity for Prompt Surgical Interference in Typhoid Perforation and Appendicitis Complicating Typhoid Fever with Report of Cases" The discussion was opened by Dr. James C. Wilson.

PRESENTATION OF A PORTRAIT OF THE LATE DR. THOMAS S. KIRKBRIDE.—At the same meeting of the College, there occurred the impressive ceremony, the unveiling of a portrait of Dr. Thomas Story Kirkbride, M.D., LL.D., who had been a Fellow of the College from 1839 until he died in 1883. The painting which is life size and an admirable likeness, was presented on behalf of the family of the late medical superintendent of the Pennsylvania Hospital for the Insane, by Dr. John B. Chapin, who is the successor in that office of Dr. Kirkbride. The president of the College, Dr. J. M. DaCosta, in a few words acknowledged the gift and returned the thanks of the College to the donors.

THE ANATOMICAL BOARD AND THE COLLEGES.—The trustees of the University of Pennsylvania, by Charles C. Harrison, the Provost of the institution, filed a bond in court in the sum of \$1,000, given to the Commonwealth of Pennsylvania for the faithful performance of their duties under the Act of Assembly relating to the use of unclaimed human bodies. It is said that the State Anatomical Board are investigating the fulfillment of the provisions of the act among the various medical colleges in this city, and will require all of them to file a bond similar to that of the University of Pennsylvania. The trustees of the University are bound as follows: "The condition of this obligation is such that if the above bounded obligators do well and truly comply with the terms and provisions of an Act of Assembly approved the 13th of June, 1883, entitled 'An act for the promotion of medical science by the distribution of unclaimed human bodies for scientific purposes through a board created for that purpose, and to prevent the unauthorized uses and traffic in human bodies,' and shall only use human bodies received by them under the terms and provisions of the said Act of Assembly for the promotion of medical science within this State, then this obligation will be void, otherwise to remain in full force and virtue."

MEDICO-CHIRURGICAL COLLEGE.—Dr. Sajous, on account of pressure of other engagements, has resigned the deanship of the Medico-Chirurgical College and has withdrawn from the faculty. Dr. Seneca Egbert was elected dean and secretary of the faculty.

RECEPTION TO THE COUNTY MEDICAL SOCIETY.—Dr. James Tyson, President of the County Medical Society, followed the very pleasant custom, introduced several years ago, of giving a reception to the members of the County Medical Society at the close of his term as president. Dr. Tyson's reception was given at the Hotel Bellevue on the 8th inst., and was largely attended. Among the out-of-town guests were Dr. Flint of New York and Dr. Howard A. Kelly of Baltimore.

CHANGE OF ADDRESS.

Avery, S. J., from 34 Washington to 780 Walnut St., Chicago.
Curry, Wm., from Palmyra to Burr, Neb.
Craig, D. W., from 1102 N. Halsted to 985 N. Halsted St., Chicago.
Gibbons, J. H., from 2052 Locust to 324 S. 19th St., Philadelphia, Pa.
Greenebaum, E. C., from 468 E. 42d St. to 29th and Groveland Ave., Chicago.
Gibson, A. L., from 233 5th Ave. to 101 E. 25th St., New York.
Hoge, M. D., Jr., from 7 N. 3d to 308 E. Grace St., Richmond, Va.
Lemon, C. H., from 449 Farrell to 465 Murray Ave., Milwaukee, Wis.
Meany, W. B., from St. Louis, Mo., to 1608 Fourth Ave., Louisville, Ky.
Mullen, T. R., from Marcus, Iowa, to Eddy Bldg., Bloomington, Ill.
Murray, S. J., from 207 Washington Park, Brooklyn, N. Y., to Charlestown, N. Y.
Mattison, F. C. E., from Chicago to Pasadena, Cal.
Peterson, R., from Grand Rapids, Mich., to 4621 Woodlawn Ave., Chicago.
Silverberg, G. M., from 465 Marshfield to 314 Center Ave., Chicago.
Taylor, J. T., from Acworth to Bedford, N. H.
Yeager, F. N., from 2400 Oxford to 2826 Oxford St., Philadelphia, Pa.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from December 22, 1897, to January 7, 1898.
 Capt. William O. Owen, Asst. Surgeon, leave of absence granted is extended one month.
 Major Louis Brechemin, Surgeon (Ft. Sherman, Idaho), leave of absence granted is extended two months.
 First Lieut. Alex. S. Porter, Asst. Surgeon U. S. A., is granted four months' leave of absence.
 Major Charles K. Winne, Surgeon (Ft. McHenry, Md.), is granted leave of absence for one month on surgeon's certificate of disability, with permission to leave the Department of the East.
 Major Egon A. Koerper, Surgeon (Ft. Crook, Neb.), is granted leave of absence for one month, to take effect on or about Jan. 4, 1898, with permission to apply for an extension of two months.
 Capt. Charles F. Mason, Asst. Surgeon (U. S. Military Academy, West Point, N. Y.), is granted leave of absence for two months and seven days.
 First Lieut. Peane C. Howard, Asst. Surgeon, will be relieved from duty in the Dept. of Dakota when his services are no longer required at Ft. Custer, Mont., and will proceed to Ft. Crook, Neb., and report for duty at that post.
Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending January 8, 1898.
 P. A. Surgeon A. Farenholt, detached from the New York navy yard and ordered to the Puget Sound naval station.
 P. A. Surgeon F. W. Glenn, detached from duty at the Puget Sound naval station and ordered to the "Mohican."
 Asst. Surgeon T. W. Richards, ordered to examination for promotion January 17 and to the New York navy yard.

ORIGINAL ARTICLES.

THE ORIENTAL EUNUCHS.

BY EDMUND ANDREWS, M.D., LL.D.

PROFESSOR OF CLINICAL SURGERY IN THE MEDICAL DEPARTMENT
OF THE NORTHWESTERN UNIVERSITY.
CHICAGO, ILL.

The word eunuch is Greek and derived from *εὐν* and *χω*, literally having charge of the bedchamber, i. e., a chamberlain. In Hebrew it was *Saris*, meaning mutilated; probably because the first royal chamberlains were castrated men. However, men officially called eunuchs soon began to be employed in all sorts of offices, though many of them were really not such in the surgical sense, and the word became merely equivalent to the term officer. A figure of speech also crept into use in which certain persons for religious reasons are said to have "eunuchized" themselves, who, in the opinion of commentators, underwent no mutilation, but merely lived in total celibacy, like eunuchs, as in the third class mentioned in Matthew, 19, 12. This habit of broadening the definition of words at the expense of their precision is a linguistic trait of oriental countries. The people were very fond of this figurative and hazy use of language; greatly to the perplexity of young western scholars, accustomed from childhood to the clean-cut precision of English definitions.

EFFECTS OF CASTRATION ON ANIMALS.

It will facilitate our study of human eunuchism if we first consider the effects of castration in the lower animals.

The elk.—The finest investigation ever made on this animal was carried out by the late Judge Caton, who had a deer park at Ottawa, Ill. He possessed there a considerable herd of the *Cervus Canadensis*, commonly called the American elk, though strictly speaking it is not a true elk at all, but a very large deer, like the English stag. Two of the males became dangerous from their fighting propensities, and one of them killed a man who had wandered into the park. The Judge had them castrated to reduce their pugnacity, and for two or three years observed the effects on their horns.

The course of horn growth in the uncastrated buck is this: Their so-called horns are not composed of real horny material, but of true bone, and are developed into antlers of immense size. They are shed annually, as in all the deer tribe. During the spring and summer they grow rapidly. They are then covered with skin, hair and connective tissue, and supplied with numerous large arteries and veins running between the bone and the skin. This is the stage called "the velvet." Toward autumn a narrow knobby ridge, or ring of bone, like a narrow provisional callus begins to develop around the base of each horn, which ridge

pushes out and presses hard against the nutrient vessels supplying the horn, and in some weeks obliterates them. Then the velvety skin and connective tissue covering the antlers is cut off from nutrition and dies. The bony horn itself also dies later and the dead skin dries and becomes loose, and the animal rubs it off among the trees and bushes, leaving the superb antlers in their perfected condition. The antlers now have no nutrition, except a little derived from the small interior vessels of the cancellated tissue, which are soon obliterated. They are now two immense necrosed bones and in the course of the winter undergo a separation, like any other necrosed bones, and drop off. In the spring a new pair sprouts and develops, like their predecessors. Judge Caton found that if while the young horns were in the velvet the buck be castrated the pair of horns then developing would go on, finish their growth and be shed the following winter as usual, but the next pair were never shed. The effect of the castration is to prevent the formation of the bony ring at the base. Consequently the blood vessels are not obliterated, the horns continue in the velvet, they do not die and are not shed. In our climate however the severity of the winter freezes the antlers and kills them down to a point perhaps eight inches from the skull. The frozen parts ultimately drop off and in the spring numerous small horns, like fingers, sprout up from the stumps. The next winter these are partly frozen, and so on until a pair of large knobby bunches of bone stand up on the top of the head.

So far as I know, no one has ever tried protecting these horns from the winter's cold to see what they would grow to. They would probably attain an immense size.

The ox.—When a calf is castrated he grows to be a larger and taller animal than the bull, but his neck and forequarters are thinner. His cerebellum becomes larger than that of the bull and his horns become both thicker and longer. The voice is changed in pitch while "lowing," but not while "bellowing." There are only three words, so to speak, in the bovine vocabulary: 1. The "low," with which they call each other at a distance. 2. A rough purring, which is used in speaking to each other near by and is made by a slight vibration of the vocal cords with the lips closed; it is especially used by the cow to the calf. 3. The "bellow," which is a growl of defiance.

The change of pitch caused by castration affects only the distant call in "lowing," and affects it in a directly opposite way from the voice of the human eunuch. In the latter the voice remains soprano, as in a boy or woman, while in the adult bull the voice in lowing is an octave higher than that of the cow. The ox retains the pitch of the cow's voice; but the lowing of the young bull rises a full octave when he comes to the age of puberty. The type of sound reminds one of the high falsetto voice sometimes

forced out by an untrained bass singer trying to reach a high note.

The horse.—These animals grow larger of frame if castrated young. The voice and the "bridle teeth" do not seem to be changed.

The sheep.—The "wethers," or castrated sheep do not become strikingly larger. The wool of the ram is, however, much more oily than that of the wether, the little yellow drops of oil (called lanolin in pharmacy) being very abundant, so that wool buyer's make a deduction from the price paid for rams' wool on account of the increased weight caused by the oil—or lanolin.

The cat.—These animals grow larger if castrated and are excellent mousers. They take great pains to display their hunting trophies, seeming to take a pride in them and desiring to be petted for their exploits. The voice is not changed.

The squirrel.—Naturalists state that black or gray male squirrels in fighting seek to castrate each other with their teeth, so that many of those taken by hunters are thus mutilated. As they do it only in adult life it does not materially change their general development.

The capon (castrated chicken).—These birds grow to a large size, being 50 per cent. heavier than the full-grown cocks. The flesh is delicate and very tender. Their spurs remain undeveloped, the colored comb and wattles about the head remain very small and the gay ornamental plumage of the cock is mostly wanting. Veterinary surgeons assert that capons develop a remarkable nursing instinct and that some of them will take care of a brood of chickens better than a hen.

In general terms, if an animal is castrated young he develops the distinctively male peculiarities in only a slight degree, yet some species produce much larger horns than the perfect male. The ox and the gelding do not completely lose their sexual passion, but make frequent efforts to copulate with females in heat. We will discuss the mental and physical effects on men a little further on.

EUNUCHS IN NINEVEH.

The recent excavations in the ruins of Nineveh, made by Layard and his successors have brought to light many sculptured figures of eunuchs in the retinues of the kings of Assyria. Several palaces were examined and immense numbers of bas-reliefs and inscriptions recovered. These palaces were erected at different periods not very far from 800 B.C. The portals were decorated with colossal winged bulls, and lions with human heads, while the halls and apartments were lined with immense numbers of large bas-reliefs cut on slabs of alabaster; showing historic sieges, battles, hawking excursions, deer hunts, lion hunts, scenes of worship, trains of captives and of spoils taken in war, etc. The Ninevites patronized the hairdressers to a surprising extent, and the sculptors fairly revelled in the elaborateness with which they copied, in stone, these hirsute adornments. The hair, both of the scalp and of the face, was combed neatly in the center, but elaborately waved, crinkled and curled all about the margins in a way that would excite the wonder and envy of any modern dude. The very manes and tails of the horses were treated in a similar way, and also the tufts of hair on the tips of the tails of the colossal winged bulls. Here and there along the sculptured processions, in strong contrast to the bearded men, the eunuchs stand out with their smooth,

beardless faces, fat cheeks and bald double-chins. The artists adopted these features as a conventional mode of representing them. They are quite numerous in the royal retinues, and not confined to any particular rank or department of service. They are figured as cooks in the royal kitchen, musicians, personal attendants on the king, cupbearers, foresters, gamekeepers, sword-bearers, military commanders and civil officers of high rank. In the Hebrew scriptures of this same period one of the three high officers sent by the King of Nineveh to demand the surrender of King Hezekiah, is called Rab-Saris, *i. e.*, Master of the Eunuchs (2 Kings: 18:17). At a later period the King of Babylon deputed the "Master of Eunuchs" to select from the captive Hebrew families a number of children to be brought up in the palace, probably as eunuchs and future officers of the royal retinue in Babylon. Daniel, the prophet, is designated as one of these children, and has often been believed or inferred to have been himself an eunuch, though that fact is not explicitly stated, and high Hebrew authorities disbelieve it.

THE PERSIANS.

The great historian, Xenophon, says that eunuchs in Persia were held in such high esteem that they filled offices of the greatest rank and responsibility.

Herodotus, a still earlier writer and called the "Father of History," says the Persian kings prized them most highly for their faithfulness, and entrusted them with the highest offices.

THE HEBREWS.

Eunuchs appear to some extent in the Hebrew records, under the name *saris*, but the term soon partly lost its primary meaning of "mutilated" and became shaded off into the general signification of "officer" whether the person referred to was surgically an eunuch or not. Thus in the story of Potiphar, he is called a "saris," but still he is said to have had a wife. Jewish scholars of high authority think the word had already acquired a secondary meaning, just as in modern armies there are grenadiers who never saw a grenade, and brigadier-generals who never commanded brigades. Kremer says that in modern times there have been actual eunuchs who took wives presumably for the regulation of their households, the government of their female servants, and for the dignity and comfort of a home life.

In Deuteronomy, xxiii; 1, two mutilations analogous to those of a "complete" castration are mentioned, but not as in the same person (a castration is called "complete" when both the testes and the penis are removed). The English version says: "He that is wounded (Hebrew, squeezed or crushed) in his stones, or has his privy member cut off (Hebrew, torn out) shall not enter into the congregation." Jewish commentators understand this to mean that he can not legally marry a Jewish woman.

The "Talmud," which is the literature of the rabbinical schools from 200 B. C. to 400 A. D., mentions both castration of the testicles and the mutilation of the penis. The Hebrew historian describes a successful insurrection headed by Jehu against King Joram and his mother, the talented and forceful Queen Jezebel or Izabel, as the real name probably was, for the English sound of J did not exist in the Hebrew alphabet. The account states that several eunuchs in the queen's palace sided with Jehu (2 Kings: 9; 32). This Izabel, whatever the pronunciation of her name

may be, was a Phœnician princess when she married King Ahab, and probably brought the eunuchs with her from Tyre as household servants. Some oriental scholars think that the name Izabel or Isabel, being common in Phœnicia, first went westward with the emigrants from Tyre who founded the city and colony of Carthage, and thence went with the Carthaginians to Spain. There it became a favorite name and at a later period spread all over Christendom, few persons recognizing its identity with Jezebel. Eunuchs are occasionally mentioned in other parts of the "old testament," but in fully half the cases it appears to be in the secondary sense of "officer." The moral sense of the people seems to have been averse to their production and they never became a prominent factor in the government.

ANCIENT EGYPT.

Some Egyptologists doubt whether eunuchs regularly existed in ancient Egypt until the invasions of the Persians and the Babylonians. Professor Breasted of the University of Chicago says, there is some difficulty in identifying eunuchs in the bas-reliefs and mural paintings of Egypt because of the prevalent fashion of shaving, which prevents the absence of a beard in a figure from being any positive proof of castration. Further, he thinks the mural decorations show that in early times the women were not secluded, but had great social liberty, so that there would be little demand for eunuchs. Rosellini, however, claimed to have found them on the monuments, and Lepsius (II. 126) gives a picture of two of them copied from a tomb at Beni Hassan, clearly showing their condition by their beardless and fat countenances. Further, the sacred "Book of the Dead" (xvii, 26) represents the good god Horus, as tearing out the testicles of his enemy, the evil god, Set; while Plutarch, in "Isis and Osiris" (55) says that in Koptos, in Egypt, Horus was pictured as holding in one hand the penis which he had cut off from the god Set. These quotations show that the Egyptians knew of both steps in the operation of "complete castration," and supposed that Horus made a "complete" eunuch of Set. This myth reminds one of a somewhat similar story among the ancient Greeks, that the god Chronos castrated his father Ouranos, performing the operation with a sickle made of diamond.

MORE MODERN TIMES.

As long as the Roman power remained confined to the Italian peninsula we do not find any conspicuous employments of eunuchs, though they doubtless appeared there to some extent on the Phœnician and Carthaginian trading vessels, but as the imperial power spread eastward it began to be permeated with these intriguing agents of orientalism. Among the earliest of these immigrants were the priests of the goddess Cybele, from Asia Minor, who were required by their religion to be eunuchs. In process of time various talented eunuchs exerted great influence in the affairs of government. One of them named Hermias became governor of a province in Asia Minor. The great philosopher Aristotle celebrated the fame of this Hermias in a poem which is still extant, and offered sacrifices to his manes. In the "New Testament" (Acts, 8: 27) mention is made of "an eunuch of great authority under Candace, queen of the Ethiopians."

While the capital of the Roman Empire was at Constantinople, under the Emperor Justinian, an

eunuch named Narses, born in the Armenian part of Persia, arrived and took service under the Emperor, where he gradually attained very high rank and influence. After a series of years an insurrection broke out in Constantinople which the imperial guards and troops were unable to suppress. Narses, backed by a large sum of money, got interviews with the leaders, bought them up, and by his skill and adroitness put an end to the whole trouble. Some time later the Goths overran and conquered nearly the whole peninsula of Italy. After many failures by the Roman generals, Narses was put in command of the army, and in two campaigns he drove the Goths completely out of the peninsula. This occurred in the years 552-553 A. D. He proved himself a military commander of great energy and talent. Narses was not the sole example of executive capacity among his class. There were frequent occasions when the eunuchs were all powerful at the imperial court both in Rome and in Constantinople. (*Grand Dictionnaire Universelle du XIXe Siècle*).

THE POSITION OF THE CHURCH.

Very early the church authorities began to discourage the barbarity of castration, but individuals to some extent favored it. The Patriarch of Alexandria was annoyed in the third century by a small party of fanatics named Valesians who defied his authority, and taught that castration was necessary to salvation. The celebrated Christian writer, Origen, born about 185 A. D., who was the first strong intellect to reduce Christian doctrines to something like a philosophic system, conceived that his usefulness would be greatly increased if he were an eunuch. He therefore caused himself to be castrated, which act he greatly regretted in after life. The Patriarch of Alexandria disapproved of it, and refused to admit him to the priesthood. Origen then went to Palestine, where the Sub-Patriarch of Jerusalem admitted him. Origen afterward founded a very celebrated Christian school or seminary.

At Constantinople there seems to have been no prevailing objection to eunuchs, for Nicetes, Photius, Ignatius and Methodius, all eunuchs, were made Patriarchs. However, the general sentiment grew steadily stronger against these mutilations until in 325 A. D., the celebrated Council of Nice prohibited the admission of any more eunuchs to the priesthood. The practice of making eunuchs, however, never fully died out from the laity, and when the Mahomedans conquered all the territories of the Eastern Empire they gave a tenfold impetus to the nefarious business of mutilating children to produce harem guards.

In Italy the Mahomedans got no permanent foothold, but a small clandestine business had existed ever since pagan times of making male soprano singers by castrating boys before the change of voice, which occurred at puberty. These male soprano singers were bought at high prices or employed in the opera houses and in some churches. Some of the popes forbade their admission to church choirs, but the underclergy did not fully obey them. Even down almost to the present time they were employed in the Vatican choir at Rome, but the present pope early in his reign put an end to the scandal and forbade the further use of eunuchs in the Vatican choirs. This prohibition, combined with the public sentiment of Italy has pretty well extinguished the infamous business, though Italian physicians say that a few

eunuchs are still clandestinely made in defiance of law.

In the Turkish Empire most of the eunuchs are furnished by the monastery called Abou-Gerhè in upper Egypt, where the Coptic priests castrate Nubian and Abyssinian slave boys at about 8 years of age and afterward sell them to the Turkish market. Turks in Asia Minor are also partly supplied by Circassian eunuchs. The Coptic priests before mentioned perform on the stronger part of the children what is called the "complete" operation. That is, they cut away the whole scrotum, testes and penis. The mortality of the operation is said to be very great. Clot Bey, chief physician of the Pasha, said that only one in three survived. Chardin stated that only one in seven survived. Dr. Dadirrian of New York, who practiced thirteen years in Constantinople, says he had no means of ascertaining the mortality during his residence in Turkey. Owing to so many dying on their hands, the survivors have to be sold at very high prices to cover the loss. This large proportion of deaths shows gross surgical ignorance and incompetency and the technique of the operation, unless recently improved, is very barbarous. I presume aseptic measures are among the things unknown in that quarter.

In Hindustan eunuchs are abundant among the Mohammedans of the Northwest provinces. A physician who had lived there did not think that they were common among those of other faiths. However, the *Indian Annals of Medical Science* reports them as numerous in Southern India, where they are called Kojahs.

In China eunuchs have existed for ages. The emperor has a retinue of them, which if full would number 3,000, but as a fact there are at present only about 2,000. They perform the work of the household and are divided into forty-eight classes under proper officers. All the emperor's sons and sons-in-law are obliged to keep from thirty down to four eunuchs each. Most of these servants were castrated by their parents (not always poor) between the ages of four and eight years, because it insures the children a career in which they can get a good living (Williams' "Middle Kingdom," Vol. 1, pp. 407-8).

Russia.—There are large tribes of Mahomedans in portions of Russia whose higher classes employ eunuchs, considerable numbers of whom are sold, or at least sent into Turkey, where also many Circassian marriageable girls find homes in the harems. Among the Russian Christians a secret sect or society has lately been discovered who clandestinely practice castration. They are called *Skopzi*, a word which signifies castrated.

Australia.—Reputable authors assert that the wild natives limit the increase of families by crushing the testicles of the father after his first child is born. I have not been able to verify this assertion. The plan of crushing the testicles coincides with the "squeezed" testes mentioned in Deuteronomy: xxiii; 1, and marked with disapproval by exclusion from the congregation.

PHYSICAL EFFECTS OF CASTRATION IN MAN.

Eunuchs made such in childhood grow taller and have larger frames than average men. They are also fatter. The hair of the pubes and of the face does not grow. The result is that the cheeks are round and prominent, the chin is apt to be double, and there is no beard. Those in whom the penis is removed use a tube to

assist micturition. This is probably for two reasons: 1. To convey the urine clear of the person and of the clothing; 2, to prevent the contraction of the cicatricial orifice, which, unless attended to, is in some patients prone to form a stricture. It is thought that eunuchs, like women, are less subject than men to the occurrence of stone in the bladder, and when old they are doubtless all free from senile hypertrophy of the prostate gland.

The effect on the voice.—A boy's voice below the age of puberty is at about the same pitch as that of a woman, but as puberty comes on "the voice changes," that is, it lowers its pitch as the vocal cords and the larynx enlarge, and in about two or three years is found an octave lower than that of the woman. Hence it is a favorite practice in some churches to have boys instead of women to sing soprano and contralto, and to those who care only for the pitch and not at all for the "timbre" of the voices the result is fairly good, but trained auditors are not fully satisfied. I have listened to some of the best boy choirs in this country and Europe, who rendered the pitch perfectly, but the quality, the timbre as it is called, never attains the richness and flute-like splendor found in the adult woman. The fact is the boy's voice is never a true soprano. If a vocal teacher of a large class will separate the boys from the girls and have them sing alternately he will instantly perceive that the girls sing in a flute-like tone, while the boys' voices have a slight clarinet quality, a kind of vibrant character, the forerunner of the trumpet note of the coming man's voice. Eunuchs preserve the high pitch of the boy's voice and often make effective singers, but yet it is the vibrant boy tone, a voice slightly mixed with the reedy clarinet timbre. There is no truly pure and glorious soprano to be had on earth except from a woman's voice. Yet some of the eunuch vocalists were very fine. Those who heard the Vatican choir some twenty-five years ago may remember a stately, almost gigantic, eunuch soprano with a voice of great sweetness and tremendous power. Still it was vibrant and not a pure flute tone, but it was excellent. He was probably the last of his kind to lift up his voice in the Vatican.

MENTAL EFFECTS OF CASTRATION.

I have not found in ancient writers any tendency to stigmatize eunuchs as feeble-minded, but modern authors indulge in the most absurd and contradictory statements on this subject.

The effect on sexual desires.—Some writers assert that if castrated young the eunuchs remain perfectly indifferent to female attractions, and articles are often written in medical journals advocating the castration of sundry criminals in adult life under the assumption that their sexual temptations will all be removed by the simple ablation of the testes. The Turks, however, have no confidence in that kind of moral reform. They require that their eunuchs shall be castrated in childhood, and that the operation shall remove scrotum, testes and penis all at one fell sweep. The Roman poet, Juvenal, alleged that in simple castration of the testes the eunuch, excited by "soft kisses," could still obtain an erection and gratify his desires, "without there being any necessity for an abortion afterward" (*Satire vi*, 366).

The fact appears to be that men castrated in adult life often retain a troublesome amount of sexual desire, and that even if it is done in childhood there is by no means a total absence of it, though it is much lessened.

Moral qualities.—Here come in a host of contradictions by careless observers. The Persians, Assyrians and Romans evidently entrusted the highest responsibilities to their eunuchs with success, which implies that they were not at that time weak, deceitful and corrupt beyond other men, as those of Turkey are now accused of being. I suspect the difference in training had much to do with the contrast in results. According to the book of Daniel, the king of Babylon sent the chief of the eunuchs to select boys from the best of the families of his captives. They were removed to the royal palace and apparently supported, educated, trained and carefully brought up to become counsellors and officials of the empire, and if any or all of them were made eunuchs, they might be expected to be very different from the Nubian negro boys now bought and castrated for market by the Coptic priests. However, I have not been able to ascertain what degree of training and culture is actually given to these young negro eunuchs. "Le Grand Dictionnaire Universelle du XIXe Siècle," says of them: "They get ahead by servility and not by talent." The "Cyclopedia of Religious Knowledge" says: "Eunuchs are jealous, intriguing, shameless, peculiarly subject to melancholy, and many commit suicide." Smith's "Dictionary of the Bible," in the article on eunuchs, says of them. They are full of "a blind, malignant jealousy. They are defective in courage, gentleness, shame and remorse, and develop malice, melancholy and a tendency to suicide." The "blind malignant jealousy" attributed to eunuchs seems absurd. Of all men in the world, why should an eunuch be jealous?

Dr. Dadirrian of New York, a highly educated Armenian physician, who practiced thirteen years in Constantinople, and knows many eunuchs, says: "To my knowledge they are brave, faithful and accurate in their duties. The Chief Eunuch can always communicate with the Sultan personally and is held almost equal to the Grand Vizier. The eunuchs' position is always very high and the ladies of the harem treat them very kindly. They are melancholy, not from ill treatment, but because they feel their isolation and deprivation of manly enjoyments." Dr. Dadirrian says that the common statement that they are malignantly jealous is an amusing blunder of western travelers, who do not understand the laws and etiquette of Constantinople. The truth is this: When any of the ladies of the harem go out to ride, one or more eunuchs go with them as protectors, sometimes on horseback, sometimes on foot. Now in Constantinople it is a serious insult to any royal lady, and through her to the Sultan, to stare intently at her in passing. The eunuch's official duty is to protect her from that or any other insult by instantly attacking the offender, whom he may beat or even kill, and no questions will be asked. Western travelers seem to have supposed him to be actuated by "malignant jealousy." The fact is there is no more personal jealousy in him than there is in a paving stone. He is simply doing his official duty as a harem guard, and he takes pains to execute it with such an appearance of alertness and force as will satisfy any imperial spy that may be watching him that he is an officer who understands his business and guards his ladies with what a Yankee would call "vim and snap." By continuing to do this he hopes to stand well at the palace as a protector of the ladies and to obtain future promotion.

The modern eunuchs grow up and live in a very bad

moral atmosphere, but so far as I can unravel the contradictory statements about them I conclude that if we except their weakened sexual emotions, their powers of mind are as strong and their morals as good as those of other men brought up under similar training and surroundings.

In gathering such of the above facts and references as are derived from the monuments and dead languages of the far East, I am indebted to the kindness and assistance of the Rev. Simon J. Pherson, D.D., Rev. Emil G. Hirsch, Ph.D., LL.D., Professor Carrier of McCormick Seminary, and Professor Breasted of the University of Chicago.

SYPHILIS.

A Clinical Lecture to Members of the American Medical Association, Delivered in the Medico-Chirurgical Hospital of Philadelphia.

BY JOHN V. SHOEMAKER, M.D., LL.D.

PROFESSOR OF SKIN AND VENEREAL DISEASES IN THE MEDICO-CHIRURGICAL COLLEGE AND HOSPITAL OF PHILADELPHIA.
PHILADELPHIA, PA.

I have present today several well marked examples of constitutional syphilis. I bring them before you not because they are rare types, but because they collectively represent some of the most characteristic phases of the disease.

MACULAR SYPHILIDE.

This young man, 22 years of age, contracted a chancre three months ago. The period of incubation was sixteen days and the lesion lasted three weeks. Nine weeks and a half after inoculation, having regarded himself in the meantime as entirely well, he noticed that his hair came out when he used the brush. He also found a few small scattered papules upon his scalp. The hair has continued to fall and is now quite thin. The papules are of a coppery color. Upon his back and sides I observed what the patient had not yet detected, viz., a macular eruption. There have been no osteocopes or noticeable fever. His throat has felt sore for several days past. The mucous membrane is erythematous and there are two or three minute erosions.

This case illustrates several points in connection with syphilis. The manifestations are mild, they have existed but for two and a half weeks and there is a distinct history of infection. An admitted exposure followed sixteen days later by a single sore upon the penis, the presence of small, hard and painless inguinal enlargement, loss of hair, an eruption upon the skin and soreness of the throat can signify nothing else than syphilis. The sore upon the penis was undoubtedly a chancre. Yet he tells me that after the lesion was healed he thought that he was completely cured. He was not aware that there was any relationship between the chancre and secondary outbreak. He had not perceived the exanthem. Now, unless he be sufficiently instructed as to the beginning and persistent nature of the malady which he has unfortunately contracted, and submit himself to a thorough, systematic prolonged course of treatment, he will be subject to frequent relapses and become a menace to every one with whom he is brought into intimate contact. On the contrary, if after its importance is explained to him, he will faithfully regulate his habits and conform to instructions, the present manifestations will rapidly disappear and he will eventually be cured.

The predominant rash upon the body is macular,

but the polymorphous character of syphilis is shown by the coexistence of small papules upon the scalp and shoulders. He has come to us in good time. In a few days without treatment the erosions of the mouth would become distinct syphilitic ulcers. He shall be warned as to the manner in which he might communicate the disease to innocent persons, and be placed at once upon the protiodid of mercury. As he is a robust individual I shall combine with the specific the tartar emetic and a small dose of powdered opium, as:

R Antimonii et potassii tartratis. . . . gr. v. 32

Hydrargyri iodidi viridis. 96

Pulveris opii gr. xv. 96

M. et ft. pilulæ No. LX. Sig.—One pill three times daily.

The antimony favors the action of the mercurial and the opium restrains its influence upon the bowels. At the end of a week the patient shall be directed to take a fourth pill at bed time. At the end of three weeks the tartar emetic shall be discontinued and the green iodid be given continuously for three or four months. At the expiration of that period if no manifestation of disease are present the drug may be advantageously suspended for two weeks, or at least given in diminished doses, as one-sixteenth grain twice a day. The full dose is then resumed for another period of three or four months. After the lapse of a year the specific may be discontinued for a longer interval. In this manner by promptly producing a decided mercurial impression and subsequently suspending or diminishing treatment during stated intervals, the virus of the disease will in most cases be totally eradicated by the end of the second year. The opium need not be continued uninterruptedly. Some writers deprecate its use and advise a combination with tannic acid or the administration of mercurious tannate. A small dose of opium, however, will prevent intestinal pains as well as check diarrhea.

When mercury is given in this guarded manner it seldom excites pyalism. A serviceable precaution also to observe in this connection is scrupulous care of the patient's mouth, which should be frequently cleansed with mild astringent and antiseptic mouth-washes.

The form in which the mercurial is given is of minor importance provided that enough be absorbed to antagonize the disease. The tiny ulcers within the mouth may be effectively touched with solutions of nitrate of silver, nitrate of mercury or sulphate of copper of suitable strength. The patient should abstain entirely from tobacco and alcoholic liquors. A stimulant hair tonic will facilitate the return of the hair. All local treatment, however, is simply accessory.

MACULAR AND PAPULAR SYPHILIDE.

A second man, 23 years of age, exhibits an abundant, symmetrical, copper colored, polymorphous rash upon the trunk and limbs. There is a predominance of small papules, but macules, large papules and pustules are also present. Prior to the evolution of the rash the man suffered from headache and aching pain over the upper part of the sternum. He has of late lost eighteen pounds in weight. He has a sore throat of the erythematous type. The patient contracted a chancre two and a half months ago, and the sore was treated at that time in our dispensary service. The eruption has been present for about five weeks. There are enlarged glands in each groin. The rash is attended by some itching, especially in the evening. Absence of itching is given as one of the diagnostic signs of a

syphilide, but the rule, though general, is not absolute. From time to time I meet with a case of itching syphilide.

This case is of some individual interest in contrast with that of the first patient. In both instances the infection dates from nearly the same time. The disease, however, has made more rapid progress in this case, probably owing to the social conditions and habits of the young man. Though the small papular syphilide develops not much later than the macular, yet the large papules and pustules usually belong to a later period. When pustules occur early in the course of syphilis they generally indicate decided constitutional depression.

The treatment of this case will be conducted upon the same principles as the first. A mildly astringent gargle will be ordered, not as having direct therapeutic value but for the reasons already given. On account of the progress which the disease has made I will make use of the corrosive sublimate, as:

R Hydrargyri chloridi corrosivi gr. iij 20

Glycerini 32

Syrupi sarsaparillæ compositæ. . . . 5 iij 96

M. ft. sol. Sig.—Teaspoonful three times a day.

TUBERCULAR SYPHILIDE.

A young man, 24 years of age, entered the hospital on account of a tubercular eruption which has affected a large part of the body for the last two years. The lesions began upon the face and at first were small. They are at the present time of various sizes, solid and semisolid in consistence. Many of them have broken down to form ulcers and a number of cicatrices are seen upon the face. In other places the eruption is in more active progress, ulcerated lesions appearing upon the surface.

This case differs altogether from those which I have already brought before you today. The man professes, and I see no reason to doubt his word, ignorance of the manner in which the disease was acquired. The lesions have been steadily growing worse for some time and cause him great distress of mind. He is extremely anxious to be cured and perfectly willing to throw all the light he can upon his case. However, he knows nothing of its origin. At his age the history can not be obscured by the mists of time. In old "rounders" of forty and more, who have pursued a course of venereal alcoholic dissipation, in whom syphilis has never been cured but recurs in various guises from time to time, we often fail to obtain any definite history of the origin. Chancre, chancreoid and mucous patches have upon different occasions involved the virile organ. It is almost a hopeless task to endeavor to distinguish an orderly and characteristic sequence of events. Tubercles, rupia and gummata point nevertheless to a syphilitic origin. We feel that we can make no mistake in adopting specific combined, it may be, or alternating with tonic treatment. Here, however, we have a patient in the flower of youth as far as mere years count. It does seem strange, indeed, that there is no reminiscence of primary disease. The man has been an industrious mechanic and has not been given to sexual excesses.

If I have seemed to assume the diagnosis it is because I have already had the opportunity of convincing myself of the nature of the malady. In fact what other disease than syphilis could cause such lesions? It is possible to form an opinion by exclusion. Tubercular lesions are common to syphilis, lupus vulgaris, lepra, carcinoma and certain rare forms of cutaneous

disease which need not here be taken into consideration. Leprosy need not long engage our attention. A stray case is now and then seen in Philadelphia, it is true, but the patient is a foreigner or one who has lived abroad. Leprous tubercles grow more slowly than those of syphilis, occasion a more hideous deformity, and moreover are characterized by more or less anesthesia. Lupus vulgaris generally begins before the twenty-second year, the tubercles are small and soft; the ulcer of lupus is superficial as a rule, and the scales are thin. Rarely in lupus should we see so disseminated an eruption. Cancer may be thrown out of question on account of the youth of the patient, the number and distribution of the lesions.

The diagnosis established, the next point concerns the treatment. The tubercular eruption belongs to the tertiary stage. As a general rule it is benefited by the administration of the corrosive chlorid of mercury combined with potassium iodid. There are, however, cases now and then encountered which prove unamenable to such a course. In such instances I have often derived benefit from the use of vegetable alteratives and tonics given until the secretions have improved. The specific treatment can then be resumed with greater advantage. In this case I shall adopt, provisionally, the method which is ordinarily attended by success, and prescribe:

R	Hydrargyri chloridi corrosivi	gr. iss	10
	Potassii iodidi	ʒ iij	12
	Syrupi zingiberis	ʒ j	32
	Aquæ	ʒ iij	96

M. ft. sol. Sig.—Dessertspoonful three times a day.

MOIST PAPULES.

In a fourth patient, likewise a male, 25 years of age, syphilis displays itself principally upon the mucous membrane of the mouth, leaving the skin almost intact. There are a few papules and pustules upon the back, and presumably from the man's somewhat indistinct account there has been a generalized eruption. He has been afflicted with sores in the mouth and upon the tongue for the last three months. There is no history of primary disease. He is not conscious of ever having had a chancre, but about a year ago he suffered from an attack of gonorrhea. Coincident with the attack the inguinal glands enlarged but did not suppurate. Shortly afterward he lost much of his hair and also had sores in the mouth. It is probable that he had a urethral chancre coexistent with the gonorrhea. At all events the history is well nigh conclusive as to syphilis infection, and it is strongly corroborated by the clinical evidence. Upon the roof of the mouth is a typical mucous patch, and ulcers are seen upon each side of the anterior half of the tongue extending nearly to the tip. There are also one or two just within the angle of the mouth. The moist papule, mucous papule, mucous patch or condyloma, for it is known under all of these names, is the analogue of the large flat papular or lenticular syphilide. Under the influence of the heat and moisture of mucous cavities this lesion is modified in its aspect and mode of growth. It flourishes within and around mucocutaneous outlets. The term "mucous patch," by which it is perhaps most generally known, is appropriate, inasmuch as it is frequently due to the coalescence of adjacent papules. Around the outlet of the anus and vagina these lesions may assume large proportions and a most repulsive appearance.

I have said that upon the roof of the mouth is a

typical mucous patch. Now a mucous patch is characteristic only of syphilis. It occurs in no other disease. Nor is it usually difficult to recognize. This lesion is generally raised a little above the level of the surrounding surface, though in some cases it is depressed. Moist papules are soft and smooth; sometimes they are of a deep red color and again they are grayish, as if the surface had been touched with nitrate of silver. They are sometimes the seat of luxuriant papillary outgrowths. Mucous patches may develop between the toes, in the groins and about the umbilicus.

This lesion is one of the most constant of syphilis. It exhibits an inveterate tendency to recurrence. Long after all marks of the disease have disappeared from the skin we may, to our disgust, witness the return of the mucous patch. So notorious is this characteristic that Jullien, with that epigrammatic terseness so highly valued by French writers, and which is so emphatic, declares the average course of syphilis to consist of a chancre, a macular rash, mucous patches, relapses of mucous patches, more mucous patches.

The same disposition to recur is seen in the small ulcers so common in the mouth during the secondary period. Much of this obstinacy depends upon irritation due to tobacco, alcoholic drinks, and carelessness in the toilet of the mouth.

Another peculiarity makes the mucous patch remarkable among the lesions of syphilis. Next to the primary infecting sore, the chancre, it is most responsible for the spread of the disease. It is the great source of extra-genital syphilis. Innocent embraces and lascivious dalliance alike spread infection when mucous patches are present in the mouth.

Local treatment expedites the cure of mucous patches or rather, I should say, their suppression, for they are never entirely cured until the disease which produced them is extinct. Solutions of silver nitrate, copper sulphate and mercuric nitrate are among the most justly prized applications. The official solution of mercuric nitrate, diluted with eight to twelve parts of water is often of speedy benefit, and I will make use of it in this case. In advanced secondary syphilis Gibert's syrup is an excellent remedy. This combination consists of the red mercuric iodid or biniodid, together with potassium iodid. It may be thus ordered:

R	Hydrargyri iodidi rubri	gr. j	66
	Potassii iodidi	ʒ ss	16
	Aquæ destillatæ	ʒ iij	8
	Syrupi	q. s. ad.	ʒ vi 196

M. ft. sol. Sig.—Dessertspoonful three times a day.

This patient shall be forbidden to use, above all to chew, tobacco. He should also avoid spiritous liquors. Every subject of mucous patches should be informed of the danger that he may spread the disease by kissing, common use of table utensils, etc.

In unusually obstinate or in "galloping" syphilis we may advantageously have recourse to other methods. Our aim being to saturate the blood rapidly with the antidote we may have recourse to mercurial inunction or to hypodermic injections. The former procedure is no doubt efficacious, but it is in many respects inconvenient to carry out in private practice. Hypodermic injections are cleanly and avoid the publicity which is so apt to attach to inunction. A host of mercurials have been recommended by different writers. I have had a large experience with this method of treatment and believe that no preparation surpasses the bichlorid in efficiency. I dissolve 4 grains of corrosive chlorid in an ounce of water and

inject 5 minims of this solution, increasing the dose minim by minim every second or third day until improvement or a constitutional effect of the mercury occurs.

SOME OBSERVATIONS ON THE TREATMENT OF TABES DORSALIS.

BY DANIEL R. BROWER, A.M., M.D.

Professor of Mental Diseases and Therapeutics, Rush Medical College;
Professor of Nervous Diseases Woman's Medical College (Northwestern University); Professor of Mental and Nervous Diseases, Post-Graduate Medical School.
CHICAGO, ILL.

The treatment of any disease, as a matter of course, is largely based upon its pathogenesis; and while we may safely assume that at least 90 per cent. of the cases of tabes dorsalis have an antecedent syphilitic history, yet it is not a true syphilitic disease, for in the remaining percentage of cases other etiologic factors are at work, among which are trauma, the acute infections, alcoholism, and the auto-intoxications, so that we may call the disease rather a degenerative sequela of these various processes, and we know not whether the disease begins in the neurons, in the connective tissue, or in the blood vessels. But let it begin where it may, the resultant is a sclerosis terminating in hypertrophy of the connective tissue and a destruction of the sensory neurons of the spinal cord. I am of the opinion that with many a too gloomy prognosis is made. In my experience the arrest of the disease is not infrequent, when the treatment is commenced in the pre-ataxic stage, and considerable improvement is possible even when the second and third stages of the disease have been reached prior to its commencement. The disease does not always interfere with the very successful use of the inherent powers of the patients. I have one patient who, since the pre-ataxic stage began about twenty years ago, has carried on a large manufacturing concern, employing at times several hundred men, and has accumulated a large fortune. I have another patient who, since the disease began about fifteen years ago, has attained eminence as a lawyer and as a politician, and has been the Governor of a great State, and is still in the active pursuit of his profession.

Treatment.—The first consideration in the treatment is the climate, and whenever it is practicable, as it often is in a great country like the United States, a warm, dry, equable climate of low level or moderate altitude should be selected as the place of permanent residence for the patient.

If the case is not advancing rapidly, an ocean voyage, giving the maximum amount of fresh air with a minimum amount of exertion, is often beneficial. I am in the habit of recommending to my Chicago patients, when possible, to spend two or three of the spring months in the Ozark Mountains of Missouri, in the mountains of North Carolina, or in a similar moderate altitude; or at Atlanta, Ga., or Los Angeles, Cal., or in similar low level climates, thus avoiding the cold and dampness and exceedingly variable climates of this season of the year in this locality.

The next important consideration is rest. When the disease is advancing rapidly, absolute rest in bed, with daily massage and the faradic exercise of the muscles is indicated, and this may often be continued with advantage for six or eight weeks, and then

patients gradually resume their ordinary avocations; and in every case I think a portion of each day should be spent in the recumbent position. I advise business men to provide themselves with a lounge in their office, and spend at least one hour in the recumbent position, and in this position they can transact much business, and at the same time give rest to the spinal cord. Excessive mental work and physical fatigue should be avoided; sexual excesses are especially harmful and seem to contribute to the production of optic nerve atrophy; whatever exercise the patient takes should always stop short of fatigue. Traumas being of serious consequence, especially concussion of the spine, should be avoided with great care. The training of the muscles in the work of co-ordination, as proposed by Fraenkel, I endorse, and advise various exercises, such as he proposed, for an hour or an hour and a half daily, and it is surprising what amount of power of co-ordination will be regained by the judicious following of this teaching.

The gastro-intestinal tract demands special attention; lavage and bowel irrigation are often indicated. Gastric crises are provoked by indigestion and colonic impaction. Food, therefore, should be easily digested, and constipation should be avoided. A change of life from one of activity to one of inactivity, forced upon the patient by the disease, tends to develop gout in those who are predisposed to it, and this should be constantly borne in mind and the diet regulated accordingly. Excesses in alcoholics and in smoking should be avoided. Electricity, especially the static form, from a machine of high potential, by insulation and by heavy sparks from the spine and lower extremities, is usually of very much service. Faradization of the skin by the wire brush electrode is also beneficial. These two forms of electricity, in my judgment, are very far superior to galvanization. When the bladder or its sphincter is weak faradization of this organ is often of service.

Suspension, first brought to our notice by the Russian physician, Motschutkowski, is of service when the disease is advancing after a more or less lengthened stationary period. I am sure that it is of service, although the practice is being abandoned by a great many. Stretching the sciatic nerves by manipulation, in the same class of cases gives results somewhat similar to suspension. Cold or tepid baths at a temperature not to exceed 96 degrees F., especially with jet or shower accompaniments are useful. A hot bath, in my judgment, is often very injurious.

In those cases of tabes dorsalis in which the symptoms have developed very rapidly and the syphilitic infection is recent, vigorous antisiphilitic treatment is beneficial, and it should consist in the largest possible doses of the iodid of potassium together with the hypodermatic use of mercury. But in those cases of locomotor ataxia where the development has been slow, and where a long interval has elapsed since the primary symptoms occurred, I am sure that this form of medication often does great harm. An alterative on which I place the greatest reliance in the chlorid of gold and sodium. I think that this drug has some power in arresting the progression of connective tissue hypertrophy in the spinal cord, as well as in the liver and kidneys. I am in the habit of giving this drug in the tenth of a grain doses (.006 gram), three times a day, and usually combine it with the resin of guaiac (.18 grams). Chlorid of gold and sodium is a very unstable drug and great care should

be exercised in its preparation by the pharmacist and in its administration by the physician. It is my practice to have the drug rubbed up dry with the pulverized resin of guaiac placed in capsules, and given one hour before meals; or, in more urgent cases, I have it prepared freshly in solution and use it hypodermatically, thus hoping to avoid by the one method or the other the destruction of the drug in the stomach. This drug being a tonic, as well as an alternative, it is indicated in the several stages of the disease and may be continued with advantage for months at a time.

The next drug upon which I place reliance is a preparation of phosphorus, and for this purpose prefer the phosphid of zinc. This I give in the eighth (.008 gram) or tenth (.006 gram) of a grain doses, three times a day after meals. As a tonic and alternative, in alternation with the above I use arsenic, preferring the arsenate of sodium in about the twelfth of a grain (.0054 gram) doses, to any other of the preparations of arsenic.

When the disease has taken upon itself a rapid developmental state, full doses of ergot with the rest before indicated will sometimes stop the rapid progression of the disease. For the pains I have found that extract of cannabis indica, injections of cocain, and acetanilid alone, or in combination, are the most successful. I have seen no especially beneficial results from the use of nitrate of silver, aluminum chlorid or of mercury in ordinary cases, and my experience is emphatically against the use of strychnia in this disease. I am very confident that I have seen more than one case very greatly injured by the use of even ordinary doses of strychnia.

GUMMATA OF THE HEART IN A CASE OF CONGENITAL SYPHILIS.

FROM THE PATHOLOGICAL LABORATORY OF RUSH MEDICAL COLLEGE.

Read before the Chicago Pathological Society, Jan. 11, 1897.

BY E. R. LECOUNT, M.D.

DEMONSTRATOR OF PATHOLOGY.
CHICAGO, ILL.

The following case is of interest as an instance of a lesion observed very infrequently, viz: gummata of the heart as a feature of congenital syphilis.

A child born at term, of young parents, died almost immediately following birth and was sent to the laboratory of Rush Medical College by Dr. A. B. Strong, of Chicago, in whose practice the case occurred and to whom I am indebted for the opportunity of making the examination.

Autopsy Abstract.—Weight 2,500 gm., length 50 cm.; the umbilical cord showed a recent ligature. The external surface of the body was the seat of a vesicular and pustular inflammation, most marked over the face, hands, feet and buttocks. The contents of these eruptions, although generally clear, were occasionally seropurulent and less often of soft, cheese-like necrotic material. The peritoneum was normal and its cavity empty. The thymus weighed 7.5 gm., and possessed several softened areas containing gray viscid pus.¹ The thyroid, submaxillary and parotid glands were normal in appearance except for an excess of blood. The pleural cavities were empty. The lungs contained numerous firm, white nodules, some of them

as large as cherries. On section these presented a smooth surface and appeared of equal consistency throughout. The lung tissue was non-crepitant or very slightly crepitant, fairly firm and oozed dark blood. The pleura over the left lower lobe was roughened by an easily removable fibrinous exudate. The liver was engorged with blood and extended to the level of the umbilicus. The spleen was slightly enlarged and congested; the pancreas was negative; the kidneys, stomach, intestines, lymphatic apparatus and the central nervous system all appeared unchanged.

The lines of ossification in both long and flat bones were irregular, wider than normal, and hemorrhagic.

The heart.—On the anterior surface of the heart midway between the base and the apex, involving that part of the ventricular wall which faces toward the left, and also overlapping the ventricular septum, was a white area, quite circular in form and measuring approximately 1 cm. in diameter. The edge of this white area fused gradually with the adjacent heart tissue, and on section appeared less firm than the unchanged myocardium (Fig. 1.) It was seen to involve the entire thickness of the ventricular wall, spreading out more as it approached the pericardium, which was unchanged except as to color. The change in the muscle also extended into the columnæ carneæ of the left ventricle. On the posterior or diaphragmatic surface, near the right border of the heart, were situated three smaller but similar areas.

FIG. 1.—Gumma near the interventricular septum.

The heart cavities contained considerable blood partially coagulated. The valves and orifices showed no changes.

Anatomic diagnosis.—Congenital syphilis, syphilitic interstitial pneumonia (nodular); syphilitic osteochondritis; gummata of the heart; pustular syphilides of the skin; multiple abscesses of the thymus; hyperemia of the liver and spleen.

Microscopic examination.—The presence of syphilis was confirmed by the examination of the viscera, characteristic changes being found in the liver, lungs, spleen and lines of epiphyseal ossification. In sections made through the large lesion on the anterior surface of the heart, the following changes were found: Between the heart muscle fibers throughout the area, which to the naked eye appeared white, there existed a marked infiltration of round or partially fibrillated cells, with faintly staining vesicular nuclei. Although the change prevailed throughout it was most marked around the blood vessels (small arterioles). The change here began immediately outside the media, where distorted cells and cells of peculiar shapes, with faintly stained nuclei occurred. These were evidently formative cells, and resulted from proliferative

¹ The mixed infection which had resulted in this case was investigated by Mr. H. G. Wells and reported by him to the Chicago Pathological Society (Transactions Chicago Path. Soc., Vol. II, 1897).

changes in the adventitia (Fig. 2). Occasionally mitotic nuclear figures were here met with.

A marked proliferation of the subpericardial connective tissue had also taken place and the resulting new cells had invaded the heart muscle to a considerable depth. The phenomena observed resulting from leucocytic invasion were: 1. Leucocytes of the polymorphous variety in transit through the vessel wall (Fig. 2). This was distinct and frequent, resulting

FIG. 2.—Showing the proliferation of the adventitia. *a*, intima of a small arteriole; *b*, nuclei of the muscle cells in the tunica media; *c*, leucocytes; *d*, muscle fibers.

in, 2, accumulations of leucocytes in the adventitia among the formative cells. 3. The occasional presence of single leucocytes at long distances from the vessels where all changes were slight and, 4, the accumulation of leucocytes in foci in which degeneration and necrosis of heart muscle fibers had taken place (Fig. 3). Not only had muscle fibers disappeared in such areas, but in some foci nuclear fragmentation of all the cells in the center of the focus had resulted and dust-like chromatin elements of the degenerated cells occupied that region. No bacteria were found in these foci of necrosis. Multinuclear cells were present in the perivascular cell increase, but the nuclei of such were closely set together and showed no peripheral arrangement or central necrosis as is so frequent in the giant-cells of acquired syphilis. No changes were found in or about the veins or in the endocardium.

FIG. 3.—Area of necrosis and round cell infiltration. *a*, leucocytes.

The literature on congenital syphilis of the heart has been thoroughly summarized by Ludvig Hektoen in a case recently reported of "Multiple Foci of Interstitial Myocarditis in Hereditary Syphilis" (*Journal of Pathology and Bacteriology*, Edinburgh and London, January, 1896), and a search through the *Index Medicus* revealed no additional cases reported since his summary. The author above mentioned was able to find only nine previously recorded cases of hereditary syphilis of the heart, and these were collated in the well-known treatise by Mracek.² In 112 cases of heart syphilis considered by Mracek, nine had to do

with hereditary syphilis and the syphilitic nature of some of these was doubtful.

Conclusions.—That this is an instance of syphilitic myocarditis is conclusively proven by the changes present in other viscera and the syphilitic osteochondritis. The title of "gummata" is simply a matter of preference; multiple foci of interstitial myocarditis with leucocytic invasion, areas of degeneration of the heart muscle and the occurrence of multinuclear cells resulted in areas which to the naked eye were of limited extent, whitish, and appeared softened, in other words, gummatus.

WHAT WE EAT AND WHAT IT COSTS.

BY D. H. GALLOWAY, M.D.

CHICAGO.

Few of us have any idea of the number of kinds of food which we eat in a year or of their absolute or relative cost. Man is said to be an omnivorous animal and this is generally taken to mean that he eats about equally of animal and vegetable food. The feeding of people collectively, as in the large public institutions, is not a test of the amount and variety of food consumed by the average man nor of the cost of it. Some time ago one of the Chicago papers instituted a prize competition for the best bill of fare which could be furnished for \$500 a year for a family of five persons. This brought forward a great many statements of the cost of living. Some of these were doubtless accurate, while many others bore such evidence of inaccuracies as to make them worthless.

There is no question but that some persons habitually eat vastly more than others; one family may eat more expensive food than another without necessarily being better fed; in fact the value of food may be in inverse ratio to its cost. While in college I had a roommate who weighed 250 pounds, which was just about twice my weight. We occupied the same room, were about the same age, attended the same classes and in many ways our habits were similar. We took our meals at a co-operative boarding club of thirty students. Without our knowledge, some of our fellow-boarders kept a record of the approximate quantity of food which we ate in a week and they found that my heavy roommate ate more than three times as much as I did. Obese people are not always extraordinarily large eaters, but they usually are and they eat excessively of heat- and fat-producing foods. Some persons eat too little and keep their vital fires too low, but there are many more who eat too much.

Eating too much food, or food that is unsuitable, or at an unsuitable time or in an unsuitable manner, is the principal cause of the great number of distressing affections which go by the various names of dyspepsia, indigestion, etc., and every physician will testify to the great prevalence of these diseases in this country. Probably more suffering is caused by errors of eating than by the use of alcoholic beverages, enormous as the latter undoubtedly is. Not all they pay for is eaten by every family. The margin of waste in some is a very large factor, while in others practically nothing is wasted. In households where the culinary department is left to servants who are not constantly watched, a larger or a smaller percentage of the food cooked finds its way into the garbage can. Quantities of meat and vegetables, too small to make another meal, are thrown out and stale bread is disposed of in the same manner. In other families these things

² "Die Syphilis des Herzens bei erworbener und erblicher Lues." Arch. f. Dermat. u. Syph., Wien, Ergänzungsheft, II, 1893.

are gathered up and go into hash or soup for the next meal, while the stale bread returns in wholesome bread pudding or as toast. Material which is wasted in one family often makes a wholesome, nutritious and appetizing meal for another.

It is not, however, so much the purpose of this article to show what we might live on as to indicate what we do live on and to present a table which has been carefully prepared from accounts which are accurate and from conditions which approximate those of the average comfortably situated American family. This table is made up from the books of Dr. Bayard Holmes' private hospital. The patients in this hospital were nearly all surgical cases and it is a well-known fact that patients who have undergone surgical operations eat as heartily as laborers during the period of convalescence. With one exception, these patients were all adults. I believe this table represents wholesome diet, adequate in quantity for the average family of equal size. It covers a period of 333 days, from May 1 of one year to March 29 of the next. The average number in this hospital family was 10.67 persons, so that we have listed here food sufficient for 3,582 persons one day or one person 3,582 days. It is equal to the board of 9,813 persons one year or one person 9,813 years. The first column of figures is the amount, where the amount can be given, of the item bought during the 333 days. The second column is the cost of the first. The third column is the amount consumed by one person in one year and the fourth column is the cost of the third. Of course, 158 loaves is not all the bread which was eaten by these ten people in 333 days, but only that which was bought as bread; most of the flour was made into bread in the house. This table is absolutely accurate in the main, though there may be small errors in a few things.

In order to obtain this record, I took the grocer's and butcher's books at the close of each month, checked up each entry and put all items of a kind together on a card. These cards were then ranged alphabetically and copied into a book. An item might appear in the grocer's book twenty times during the month, but it would appear but once in the account, the amount and cost including in one entry the total for the month. Since the numbers in the first column represent the amount consumed by 9,813 persons in one year, the amount consumed by one person is found by dividing the former number by the latter. Practically, I took the reciprocal of 9,813, which is approximately .102, and multiplied the numbers in the first column by this factor to get the numbers in the third column and by the same process the numbers in the fourth column are obtained from those in the second. There are 128 items in the table.

The following table is a synopsis of the foregoing one. I have grouped the items by classes and arranged them in the order of expense. The amount

in the column of figures is the cost of the article named for one person for one year.

Meats (including fish, oysters and lard)	\$29.28082
Milk (cream and matzoon)	23.72316
Fruit (fresh, canned and dry)	10.79996
Vegetables (green and canned)	8.50791
Butter	8.44662
Breadstuffs (bread, flour, crackers and cereals)	7.55866
Eggs	7.05942
Coffee, tea and chocolate	3.60876
Sugar	3.48738
Ice	3.16200

Add together the foods of animal origin, meat, milk butter and eggs and a few more small items and we have \$69.85516 as the cost of animal food which each one of us eats in a year, against \$41.86736 for foods of vegetable origin which we eat in the same time.

It will be seen by reference to the table that in a year the average man eats 33 pounds of butter and pays \$8.44 for it, 63 lemons at a cost of \$1.45, 75 oranges at \$2, uses 632 pounds of ice at \$3.16, consumes 363 quarts of milk at a cost of \$21.23, 462 eggs at a cost of \$7 and 10 pounds of salt at 10 cents. It shows also that we spend as much for oranges as we do for potatoes, and more for fruit than for vegetables.

We paid for rent for each person \$72.93. I looked over my private accounts and found that I paid for clothing in ten years (from the time I was 20 till I was 30 years of age) \$525.73, an average of \$52.57 for each year. Taking these figures as a reasonable average I find that it costs for the three principal necessities of life as follows: Food, \$111.72; shelter, \$72.93, clothing, \$52.57.

During this time (333 days with an average of 10.67 persons) we used 37,500 matches, 399 bars of laundry soap, 79 bars of cleauing soap and 206 bars of toilet soap. This indicates that each person uses 3,750 matches a year, or more than ten every day, and this is below the real number consumed, as we had one or two thousand on hand when this account began. It will be seen also that each person uses 20 cakes of toilet soap in a year or nearly two each month. This includes bath soap, and in this hospital every patient got at least one bath every day. During the entire time this hospital was under my management there was not sent out of it one pound of garbage nor any combustible refuse whatsoever; nothing but ashes and broken glassware and crockery was put out for the scavenger. Everything combustible was made into bundles with old newspapers and burned in the furnaces both in winter and in summer.

During this period we used 92,000 cubic feet of illuminating gas, for which we paid \$99.54, equivalent to 9,384 cubic feet, at a cost of \$10.15 per person per year. I have since looked up the amount of gas consumed for lighting purposes by a family of four people and found it to be 38,400 cubic feet, which makes 9,600 cubic feet for each person, and this corresponds very closely with the previous statement.

200 Oakwood Boulevard.

THOUGHTS ON THE APPENDIX.

Read at the meeting of the Middle Tennessee Medical Society,
Nov. 18, 1897.

BY S. T. HARDISON, M.D.
LEWISBURG, TENN.

For the last decade the mind of the medical world has been turned to the region of the appendix, and possibly no part of the body has been so often before the profession for attention, both medical and surgical. The professional gentleman who has not had

numerous cases of appendicitis to treat has either been careless in his diagnosis and investigations, or has had a clientele that is far behind in medical fads and fancies. The increased frequency of troubles that involve the appendix either primarily or secondarily, has caused much thought and many theories in regard to its treatment both medical and surgical, conservative and radical.

Many learned men of wide experience have espoused the conservative course, but possibly a greater number favor prompt surgical interference. Quite a degree of success has been attained, and many are almost entitled to be called experts in its management, and if failure to bring relief is the result, it is almost always attributable to the lateness of the operation. Indeed, some have advocated the removal of the appendix as a superfluous organ, a menace to health and comfort. Doubtless, this is a wise conclusion if it has no function to perform. When I mention the use of function of the appendix, I am aware of the fact that I am approaching a subject that not only has not been investigated, but one so unimportant and prospectively so barren and uninviting as to forbid investigation. Years have come and gone, medical students with scapel in hand have carefully studied the anatomy of the appendix and have often asked the question, What purpose do you serve in the mysterious make-up and mechanism of this creature so fearfully and wonderfully made? Up to the present moment no satisfactory answer has been returned. Some have suggested that it is a rudimentary appendage, and that possibly man in his early existence had different viscera from what he now has, and as his condition changed, his anatomic make-up changed to keep in harmony with his environments. Another theory is that the troublesome appendix is an accidental formation which never had any mission. I think that both these theories are unsatisfactory and humiliating, and without intent are a reflection on the wisdom, power and goodness of Him who not only doeth all things well, but who doeth all things perfectly. No imperfections can be attributed to Him. No accident can happen to mar His work. And man the last, most wonderful and most exalted of all His creatures could not come from His hands with defects and imperfections that are unknown to the make-up of his inferior creatures. Therefore, I must be permitted to emphasize the statement that the appendix is not a useless appendage, occupying its place without use or function; and while I may not be able to explain to you its function clearly and satisfactorily and demonstrate it beyond doubt or cavil, I do hope to encourage you to examine the matter, and not cast it aside as did the builders of the temple, that stone that was to become the head of the corner, because we already know that the appendage often becomes an important tail on the corner.

Let us look for a moment at the anatomy of the parts. First, we have the valve at the termination of the ileum that prevents almost completely the regurgitation of the contents of the bowels. We have the cecum as a kind of the receptacle or depot, and the ascending colon is indeed an elevator whose power to remove the accumulations in the cecum, opposed by gravitation when in the upright position, smaller diameter, dependent alone upon peristaltic action, and the least failure on its part to do the work produces stoppage and accumulation in the cecum. Now we want more power. The colon, the elevator is ready

but no power to put it in motion. The accumulation increases so gradually that the cecum distends slowly until the imperfect valve of the appendix is open, and the contents of the cecum press in. Irritation and stimulation is the result producing contraction and expulsion. This irritation and stimulation is communicated to the cecum, and by its contraction the contents are forced up through the colon or elevator, and the depot is emptied and the appendix closes (if no grape seed or any other hard substance becomes entangled in its valve) and remains quiet and in a restful state, until there shall be a similar demand made on it, to assist in removing undue accumulations in the cecum in a similar way. This would not be necessary if man did not maintain the upright position, hence no animals have an appendix except those that maintain the upright position, viz., the wombat, orang-outang and man. This is a strong circumstance in favor of the position taken. The appendix like any other organ has a limit to its capacity. If overworked and badly treated, it will break down and fail, and instead of performing its functions it will allow the contents to remain in it, producing inflammation resulting in gangrene, not only being destroyed itself but inviting destruction upon the whole body, upon the principle that a little leaven leaveneth the whole lump. This sacred adage has never been more forcibly illustrated than in the diffusibleness of a poison germ originating in or developing in the abdominal viscera.

Another potent factor that neutralizes the function of the appendix, is slow bowels or constipation exercising its influence by the damming-back process closing up the elevator or colon, increasing the demand on the appendix beyond its capacity until appendicitis is the result, and once developed it is almost sure to return. And as slow bowels have so alarmingly increased until constipation to a degree is almost the rule or natural condition of a majority of the people this is an easy explanation as to why appendicitis has grown from a very rare affection to one of remarkable frequency. Therefore, it is not true, that it has always existed to the extent that it does now and was overlooked by our illustrious predecessors, for in all other things they proved themselves the equals of the present day of great and glorious workers in medical and scientific research. Man's habits have changed. In fact the man himself has changed. He once had a large foot and a small head. He used a number ten shoe and a number six hat. He now wants a number seven shoe and a number eight hat. There is less physical exercise and labor for him. There is more mental worry and work for him. He does not go to bed and sleep all night as did his fathers. He does not live on coarse laxative food that required much mastication, developed his teeth and strengthened all his digestive powers. Hence indigestion, constipation and appendicitis were unknown to our ancestors, and would be unknown to us if we had proper food rightly prepared, taken at proper intervals, in necessary quantities, without hurtful stimulants and narcotics and all other things that have a tendency to retard digestion. Then let us not remove the appendix, but let it remain to perform its God-given function.

Let us relieve it and protect it. Take time to eat and time to sleep and to do everything that is necessary to preserve and protect the body, and so for as this life is concerned all will be well.

PHYSICAL DEVELOPMENT OF WOMEN.

Presented to the Section on Physiology and Dietetics at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY HARRIET E. GARRISON, M.D.

DIXON, ILL.

"Our civilization is hard upon the women," remarked a highly cultivated woman as she sat in my office discussing the way by which she could be restored to her usual vigor. This remark was called forth by my insistence upon the statement that nothing but absolute rest would enable the overwrought mind and body to recover their usual tone. The family inheritance of acumen and mental vigor, which had carried a brother to a seat upon the bench of the Supreme Court of our State, had sent the sister into all kinds of philanthropic works. These, and looking well to the ways of her household, had made serious inroads upon a once vigorous constitution.

Our civilization is hard upon women only because they are in a state of transition from the wholly material to the entirely intellectual. When all that was required of woman's brain was to read a little and write sufficient to keep up a limited correspondence, she had strength and energy sufficient to develop into a healthy, hearty housewife and mother. But now our school system demands that every girl, whatever her after-life is to be, must have brains developed sufficiently to write a book, without regard to the effect this may have upon her physical development. And every woman must engage in some kind of benevolent work no matter if she is starving for outdoor exercise, fresh air and sunshine.

Is there much inherent difference between the physical capacity of the sexes? A study of the agricultural laboring classes leads me to think that woman can be trained to as much physical endurance as man. Among the foreign peasants the women work side by side in the fields with their husbands and brothers, usually doing the more laborious part of the work. It is the woman of Germany, who, hitched side by side with her faithful cow draws the plow, while the man takes the less muscular but more intellectual task of guiding it. While on a visit to "the great red pipe-stone quarry" of Minnesota, as a tribe of Indians were taking out their supply of pipe-stone, I noticed that the men cut the stone from the quarry but the women were out along the railroad track splitting discarded ties into fire-wood, and as we drove back to the town we marveled to see the immense load of wood fastened upon the back of each squaw as she returned to the camp. Among our own agriculturists I have been surprised at the amount of endurance displayed by the women. In one case a woman, the mother of four young children, after pitching hay upon the wagon all day endured the pangs of labor all night and called me in the morning; but the fetus had not yet reached maturity and I advised rest in bed after a quieting potion. But as soon as the pains were relieved she got out of bed and did the family washing and then went back into the hay field until the fetus matured, when she was delivered without the aid of an obstetrician. Again I was summoned in haste to find her kneeling beside her bed with the livid face and gasping breath of the extreme anguish of angina pectoris. Hot applications, morphia and heart stimulants soon brought relief and then I found that she was within four weeks of her ninth accouchment. Besides her usual house and field-work she had been milking six-

teen cows night and morning. In two days after I saw her she went back to her usual work and in two weeks after her delivery she returned to her place in the dairy. Nor is this an isolated case; there are hundreds of women who enjoy such work.

But these cases are in marked contrast to those we meet among our intellectual women who are semi- or whole invalids from early childhood to the grave. Some of these are born invalids, inheriting neurosis from neurotic ancestors; others have invalidism thrust upon them. While we do not care to have our women become farm laborers, we would like to have them with sufficient physical endurance to do the work, both physical and intellectual, which falls to their share without that constant tired feeling of which so many of them are continually complaining.

I think the late Dr. Frank Hamilton gave us the key to the lack of physical development in our women when he wrote: "Calisthenics may be very genteel and romping very ungenteel, but one is the shadow, the other the substance of healthful exercise. Girls need health as much, nay, more than boys. They can only obtain it as boys do by running, tumbling, by all sorts of innocent vagrancy. At least once a day girls should have their halters taken off, the bars let down and be turned loose like young colts."

If our girls were turned loose to amuse themselves spontaneously, to run up hill and roll down, to skip and jump without rhyme or reason, except as it is supplied by the exuberance of their own innocent natures, there would be less headache in adult life. Only the other day an earnest, conscientious mother asked me about her little girl of seven, whether I thought it just right for her to allow her to romp on the floor with her little baby sister. As the mother expressed the matter, the girl had grown so rapidly she looked very ungainly rolling over the floor. "So much the more need for her to roll on the floor or grass that she may grow in strength and beauty," was the advice I gave the mother. In the tall, rapidly growing girl there is not sufficient nutriment supplied to the muscles to support the trunk in the erect attitude of standing, and rolling gives exercise to various sets of muscles without overtaxing them in trying to support the trunk. Many of our girls with round shoulders and rickety spines would have been saved these deformities had they done more rolling. A few weeks ago I had under my charge a girl of 12 years who was round-shouldered and small looking. She was very sick with la grippe and developed dangerous heart symptoms, for which I confined her in the recumbent posture for two weeks. When I finally allowed her to leave her bed, her mother was astonished at her great increase in height and declared she had grown four inches while in bed. I did not suppose there had been any actual gain as she had not taken sufficient nourishment, in fact she had lost in weight and the increase in height was due to the muscles having become rested and strong enough to hold the body in perfect shape. I advised the mother to have the girl spend half the time in bed until the muscles became more fully developed.

Fresh air, fresh water and sunshine should be the inalienable right of every child in this land of the free and home of the brave, but our women are starving for these very things. Not only are the girls from the sweat-shops and factories, who are shut in for ten or twelve hours where no sunshine or fresh air can reach them, crying Hood's refrain,

"It's O, to be a slave,
Along with the barbarous Turk,
Where woman has ne'er a soul to save,
If this is Christian work,"

but the woman of social position must give at least ten hours daily to her duties, shut in as closely from fresh air and sunshine as her humble sister.

Our school authorities do not recognize the need of fresh air and exercise in the sunshine, with plenty of fresh water, but year after year try to drill into starved brains knowledge, a greater part of which is of no practical benefit to that particular individual. If the State wishes to educate the children let it make the education common. As the schools now stand the privilege is extended to but a small fraction of the children, and these are the ones who least need the State's help. Let our school curriculum be made broad enough to include development of body as well as mind; let the schoolhouses be set away from other buildings with large, surrounding playgrounds. It is not necessary for the schoolhouse to be placed at the door of the scholar's home, but let there be public conveyances to carry the scholars to the door of the schoolhouse.

Nothing which the municipality could do would elevate Mott Street in New York more than for the children to be gathered up every day and carried a few miles into the country by an electric line to a pleasant school building with a ten-acre playground arranged as a park, with hills to climb and valleys to explore, and grounds for all games; with bath-houses and swimming pools, where once a week every child is made to plunge and taught to swim. This can be done with no more expense than our present school system. It may be necessary to shorten the time in which the scholar is the ward of the State, and our sweet girl graduates with their beautiful ribbons, laces and fluffs, with their tired, drawn faces which even "opalin" will not make young and fresh, may disappear, but in their places will come the fresh glad girls, able with their strong, healthy, young bodies to fill every sphere.

With this change must come other changes. Our civic authorities must take cognizance of the physical needs of our girls and provide places, with every facility for reaching them, where girls are incited to healthy exercise with basket-ball and other hardy games. The State levies a tax for free libraries where the girls may be shut in with foul air and with literature as detrimental to their minds as the air is to their bodies. If any one doubts this statement let them look over the list of books most called for in our public libraries. We do not want to banish all public libraries, though there is a class of books which should be banished, but with these supply play places with games and bathing facilities, where every girl can engage in the healthy exercise of swimming. The plea is sometimes urged that bacterial disease is transmitted in free bathing establishments, and so is every book used in a free library covered with germs; and more dangerous germs as they are gathered from the homes of diphtheria and typhus fever. If the water is frequently changed in the bathing pools the danger of contagion is reduced to an infinitesimal quantity. In communities where there are clear running streams there are hundreds of women who never have a plunge-bath from the cradle to the grave; from birth to burial they never know the cleansing which only submersion in clear, pure water can give. Here the fastidiousness

of the community prevents the bountiful provisions of nature for woman's physical needs from being utilized; and even boys are fined for yielding to temptation of the pure sweet influence of the running water anywhere within telescopic view of the over-nice passer-by. Verily, those who do not bathe should pay the fines, as the crimes of the community are perpetrated by the great unwashed. To be unwashed for a week should be a crime. Every community too large or cultivated to use primitive bathing methods should provide free bathing facilities within its borders, and the women of the community should be urged to make use of these unless they have private arrangements for plunge-baths. Nature has clearly indicated that to be thoroughly cleansed the body must be submerged in water, even the ears which so many fill with cotton before a plunge will be none the worse for being washed out with pure water.

Let every physician assist in enforcing the law for shorter working hours for women, and urge that their free hours be spent in healthful outdoor exercise, and we will have a brighter, healthier, happier set of women.

A CASE OF VICARIOUS MENSTRUATION FROM THE LUNGS.

BY T. L. CHADBOURNE, B.S., M.D.

COLUMBUS, OHIO.

Cases of vicarious menstruation are not rare, but cases of long-standing vicarious bleeding from the lungs are tolerably uncommon.

On consulting the literature one is struck by the small number of such cases that have been reported in this country.

The *Index Medicus* from 1888 to June, 1896, has only about twenty-five distinct references, the *American Journal of Obstetrics* from 1886 less than ten, and the *American Journal of the Medical Sciences* for the same time has but one case indexed.

The chief interest of these cases lies in their connection with the question of tuberculosis. Some of them are mistaken for phthisis, while many of them really are tuberculosis, and only later develop the signs of the disease.

Thomas¹ reports a case of a patient, age 40 years, who, after twenty years of normal menstrual life, slowly began to have hemorrhages from the lungs. She lost weight greatly and had every appearance of pulmonary phthisis. Physical examination showed no signs in the lungs, but disclosed an occluded cervical canal. After operation the patient recovered entirely in six weeks.

Ford² reports a case of a patient aged 25 years, who menstruated at 15, at 19 took cold and ever since has had pulmonary hemorrhage for three or four days every month; has not lost weight.

Stuart³ calls attention to a patient with the following history: Age 15 years; menstruated at 14; tuberculous family history.

The patient suddenly began to have vomiting of blood with occasional hemoptysis. After seven months she developed signs of tuberculosis and a few months later died of this disease.

Stuart calls attention to the fact that, from the first, the case was thought to be tuberculous, although for seven months no signs could be made out.

Kober⁴ gives a very interesting case as follows: Age 18 years and 9 months; has never been ill; menstruated for two years.

February 10 she had a slight period and marked hemoptysis; was very sick at stomach. At this time she developed a mild pneumonia behind, below, which resolved in ten days.

March 4, again hemorrhage, nausea and pneumonia. Soon after this, catarrh of the right apex. A third time she had hemorrhage, with other symptoms as before. She died in June, of tuberculosis.

The hemoptysis came on at a time when no suspicion of pulmonary disease could exist, and the author insists that the prognosis in cases of recurring hemoptysis must be very guarded.

May 8, 1896, there came to the Michigan University Hospital a patient for examination of her lungs, as she was thought to have consumption.

The patient gave the following history: Age 18 years, menstruated at 14; one sister dead of spinal disease; no history of lung trouble. The patient has generally been well; three years ago had typhoid; says she has had slight hacking since. For the last year, slight yellowish expectoration, never bloody except as stated below.

Since her eighth year she has had enlarged glands in the neck. These have varied in size, have never suppurated. Have once or twice been favorably influenced by iodine.

Fifteen months ago she took cold, and the next afternoon, during a severe coughing fit, suddenly began to spit blood, which came up rapidly; for the most part rather thick, although some of it was frothy; quantity sufficient to saturate two or three handkerchiefs. Her period was due at this time. Regular flow did not occur, but she continued to spit blood for four days. She missed her next three menstrual periods, but at the times these were due she spat blood, although never so much as at first.

The regular flow then reappeared and was normal for four months, during which time there was no hemoptysis. During the five next succeeding months the hemoptysis again replaced the catamenia. During the last three months the flow has occurred in the normal manner.

The bleeding has usually occurred just at the time of the catamenia, although in one instance last winter it was delayed about a week.

With the hemorrhage she has pain in the chest and a good deal of nausea, both before and afterward. There is no disturbance of the stomach at other times.

She has slight bearing down pains during the first part of her period. The flow is scanty and she is slightly irregular, usually postponing.

Physical examination at this time showed, aside from the enlarged glands in the neck, no anomaly, the lungs being entirely negative.

May 27, she entered the hospital and, during a stay of a week, was several times examined and the following notes were made: Patient undersized; muscles in fair condition; tongue large, with thin white coating; on both sides of neck enlarged glands, varying in size from a walnut to a pea; glands in left axilla also slightly enlarged; they are elastic, not tender, not adherent; skin not reddened. Thorax long, narrow, especially below; of moderate depth; epigastric angle narrow. Lying, supraclavicular spaces are symmetric. Expansion slight but symmetric. Palpation is negative.

Percussion: Good resonance over apices and clavicles, slightly fuller left than right. Further percussion yields good resonance everywhere.

Auscultation: Normal vesicular over both apices; slightly interrupted vesicular under clavicles on both sides; normal vesicular elsewhere; no adventitious sounds.

Heart negative.

Genital tract examined by Professor Martin, who found, aside from a rather small uterus, no abnormality.

Further physical examination negative.

Urine: Small amount, negative.

Blood: Covers show some variation in the size of the erythrocytes; leucocytes 4,200; reds. 4,116,000; hemoglobin (Gowers) 70 per cent.

Although she remained in the hospital a week, no sputum could be obtained.

¹ Amer. Jour. Obst., XIX.

² Amer. Jour. Obst., XXII.

³ Journal American Medical Association, IX.

⁴ Berl. Klin. Wochenschr., 1895.

She was lost sight of till Feb. 2, 1897. She now reports herself as being in good health, weighing fifteen pounds more than last May. During the past summer she twice noticed small amounts of blood in the sputum, not at times of period; probably accidental. Physical examination at this date is again, aside from the enlarged glands, which have changed but little, entirely negative. Menstruation has been regular.

The following points seem worth noting:

1. The patient has had periodic hemorrhage from the lungs for a long time, at least nine times within a period of fifteen months, without having, up to the present date, any demonstrable signs of lung disease.

2. In view of the fact that so many such cases are later seen to be tuberculous, prognosis was guarded, the more so on account of the enlarged glands.⁵ The fact that the patient has to all appearance recovered does not make it impossible that she may still have a healed tuberculous lesion in her lungs.

239 E. Town Street.

PRIMARY SARCOMA OF THE IRIS.

A STATISTICAL STUDY, WITH THE REPORT OF AN ADDITIONAL CASE IN WHICH THE GROWTH WAS SUCCESSFULLY REMOVED BY IRIDECTOMY.

Presented in the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CLARENCE A. VEASEY, A.M., M.D.

PHILADELPHIA, PA.

Primary sarcoma of the iris is an affection so seldom met with that a report of each isolated case requires no apology. The following notes are from a very interesting case, kindly referred to me by Dr. Joseph J. Burke, from whom the growth was successfully removed by a broad peripheral iridectomy.

M. B., aged 46 years, a male, had been suffering from an inflamed left eye for three weeks when I was first asked to see him at his home. There was excruciating pain in the bulb that extended backward through the temporal region to the left side of the head, accompanied by intense photophobia on the least exposure to light, which was attributed by the patient to an attack of neuralgia. An examination, however, revealed marked pericorneal injection, a discolored iris, a contracted pupil with numerous posterior synechiae and what appeared to be a brownish growth in the upper inner quadrant of the iris. Hot compresses at frequent intervals followed by the instillation of a solution of sulphate of atropin was the treatment prescribed and the patient was told to report at my office on the following day for further examination. Upon this occasion his vision was found to be for O. D. 5-9 and for O. S. 5-27, the latter eye being under the influence of a mydriatic and the patient complaining of everything looking very foggy. The vision of the left eye was unimproved by glasses. An examination of the right eye showed it to be normal with the exception of a low refractive error, which, when corrected, gave him perfect visual acuity.

An examination of the left eye showed an evenly dilated pupil except up and in. In this portion there were no synechiae, but a small brownish tumor of the iris, somewhat ovoidal in shape, could be seen, the lower end of which was pushing the posterior pig-

ment layer of the iris downward and backward giving to the pupil the shape seen in Fig. 1. With the red reflex from the fundus as a background the position of the lower end of the growth could be distinctly observed in the pupillary space. The growth itself was not so long as the entire width of the iris, as some iris tissue seemed unaffected both on the ciliary and pupillary ends, as well as upon the sides. It had the appearance of a foreign body making a bed, as it were, in the stroma of the iris, yet entirely separated from it and pushing the pigment layer before it as it grew backward. No blood vessels could be detected passing over its surface nor could any hemorrhages be seen. The capsule of the lens was somewhat cloudy and there remained a ring of pigment spots where the iris had been attached. No family history of tumors of any kind or specific personal history could be elicited. The patient had had some necrosis of one of the bones of the leg many years before, which had been entirely cured. He has three healthy living children.

Upon examining a photograph of the patient taken eight years before, there was a suspicious looking shadow on that portion of the iris occupied by the growth that looked as if it might have been a dark spot. A history of two other attacks of "neuralgia," evidently iritis, during this period affords additional evidence that the growth had existed for some time, though unnoticed by any of the patient's friends or members of his family. For three weeks before my examination it had been increasing rapidly in size and there was present a severe plastic iritis.

FIGURE 1.

Upon consultation with Dr. George E. de Schweinitz he agreed with me that the growth was probably a primary sarcoma of the iris, but to give the patient the benefit of the doubt it was thought proper to administer mercurial inunctions and rapidly increasing doses of potassium iodid for a short time to see what effect might be obtained. These remedies were faithfully employed for one week, at expiration of which time the growth was nearly twice as large as when first seen and the iritis was fully as bad, the pain still being intense, while the lens as well as the capsule was undoubtedly becoming opaque through the backward pressure of the lower, or pupillary end.

The growth was excised with a broad peripheral iridectomy without complication, except a profuse hemorrhage as soon as the inflamed iris was cut, a bent keratome and ordinary iris forceps being employed, there being no difficulty in drawing it out with the portion of the iris in which it was embedded. A small tag of the iris caught between the lips of the wound giving some pain for a moment, but as soon as it was released the pain disappeared. The eye made

⁵ We wished to remove one of these for purposes of diagnosis, but were not allowed.

an uneventful recovery notwithstanding iritis was present at the time of operation. The opacity of the lens continued to increase until vision was reduced to light perception, when, though much clear lens substance was present, it was extracted through a three millimeter corneal flap without complication. This was about eight months after the first operation. Though the vision in the left eye, before the growth was removed by the iridectomy, equaled only 5-27, after the extraction of the opaque lens with the correcting glass vision equaled 5-6 and Jaeger 1 was easily read. So far as can be seen there has been no recurrence of the disease, fourteen months having elapsed since the growth was removed.

The tumor was somewhat crescentic in shape, being markedly concave on its inner surface and convex on its outer surface, measuring 2.5 millimeters in length, 1.5 millimeters in breadth and 1.5 millimeters in thickness. It was hardened in Müller's fluid and several sections were submitted to my friend, Dr. H. F. Harris of the pathologic laboratory of the Jefferson Medical College, who kindly furnished me with the following description of the growth and superintended the drawings, which were made by Miss Elizabeth Hard-

FIGURE 2.

ing: "Four sections of the tumor were submitted to me for microscopic examination. In general outline and size they are practically identical; in form they are somewhat kidney-shaped. In the center of each is a U-shaped open space (Fig. 2), the convex border of which corresponds with the convex border of the mass. Bounding this opening and forming the inner layer of the tumor is a continuous layer of dark pigment plainly discernible with the unaided eye. The sections of the tumor given to me are thus seen to consist of an irregular but continuous ring surrounding an irregular opening. The convex portion of this ring is more than double the thickness of the concave portion. The portion where the iris was attached is not seen in any of the preparations. This fact and the peculiar shape of the section can only be explained by the supposition that the tumor had grown forward forming a hollow somewhat hemispheric mass, the concave surface of which was lined by the pigment layer of the iris, and that segments of this mass were cut anterior to its attachments. One of the sections was stained with hematoxylin and eosin, and the others with carmin. Under a low power the tumor was seen

to consist of small round cells with a considerable amount of intercellular substance. Numerous blood vessels were seen scattered through the growth. These vessels were especially numerous in the tissue forming the thin concave portion of the ring, and were remarkable for the thickness of their walls and for the fact that they contained no blood. The vessels of the thicker portions were filled with blood, and so far as could be seen had no walls, the blood being apparently in direct contact with the cells of the tumor. Numerous dark brown pigment granules were seen scattered through the tissues of the thicker portions of the ring. This was especially marked around the outer border. The pigment layer surrounding the inner border of the tumor was dark brown, almost black in color, and while continuous, was very irregularly disposed over the surface, several bands projecting into the open space in the center of the mass.

FIGURE 3.

"When examined with higher powers the cells which compose the greater part of the tumor were seen to be small round cells with which were intermingled a few oval ones (Fig. 3). These cells were almost of uniform size, having a diameter of from 10 to 12 microns. Their nuclei were stained of an almost solid color both in the hematoxylin and carmin preparations, in no case being sufficiently well preserved or stained to show the finer details. The nuclei were surrounded by a thin rim of protoplasm in which there were often embedded multiples of small pigment growths. In many situations, notably about the center of the thicker portions of the tumor, there is a considerable amount of firmly granular intercellular substance. In several places distinct bands of fibrous tissue and minute bundles of involuntary muscular fibers can be distinguished. Most prominent along its convex border,

but scattered throughout the tumor, are numerous masses of granular dark brown pigment, varying in size from immeasurably small particles to collections having a diameter considerably greater than that of the cells which compose the tumor. From the pigment layer which covers the inner surface of the tumor numerous fine spiculæ of pigment substance are seen projecting between the neighboring cells. The tumor is, however, much less pigmented here than along the outer border and as has been before mentioned, much of this pigment is found within the protoplasm of the cells. The inner pigment layer presents the characteristic appearance of the pigment layer of the iris. The tumor is I think beyond doubt a pigmented, small round-cell sarcoma."

During the past twenty years several analyses of the previously recorded cases of sarcoma of the iris have been published, the most extensive, however, being those of Fuchs, Andrews and Werther. In 1882 the former published his classic treatise, "Das Sarcom des Uveal Tractus," in which he analyzed sixteen cases that he had collected from the literature up to that time. In a recent number of the *Archiv für Augenheilkunde*, F. Werther adds to Fuchs's list twenty-three cases collected from the literature appearing between 1882 and 1893. These tables have to a considerable extent evidently been compiled from incomplete abstracts of the original reports, as many of the important details of some of the cases have been omitted in the former but are found in the latter. In addition some of the cases have been found to be incorrectly classed; for example, when a non-pigmented sarcoma is placed under the heading "melanotic," and some of the cases were never operated on and are therefore useless for statistical purposes.

In the following list a few cases recorded prior to 1893 that seemed to have been overlooked in the previous papers, as well as those that have been reported from that date to the time of writing this paper (February, 1897), have been added. No case in which the growth was not operated on, and hence no histologic examination made has been included. Briefly, the principal points in the history of each case are as follows:

Case 1. Adams. A female, 13 years of age, was brought to the author with a small brown tumor about twice as large as a pin's head situated on the lower and outer part of the left iris. While treating with mercury the size increased and another mass appeared in the neighborhood of the first. Vision equaled 20_{50} . Several opaque spots were observed in the deeper layers of the cornea. Enucleation was performed and the growth was found to be a round-celled sarcoma.

Case 2. Alt. This case was a female 2 years of age. One month before the examination a small growth had been noticed on the right iris. The lens was cataractous. Tension at first was normal but later became elevated. There were several nodules throughout the iris, the largest being in the lower and outer quadrant. Enucleation was performed and the growth, which originated in the parenchymatous tissue of the iris, was a round-celled sarcoma.

Case 3. Andrews. The patient, a female 47 years of age, had noticed discoloration of the left iris at the site of the growth for many years. The vision of this eye had been periodically obscured for fifteen months. There was no pain and the vision of each eye equaled 20_{100} . Iridectomy was performed and was followed by suppurative of the globe requiring enucleation a week later. Microscopic examination showed that the entire growth had been removed by the iridectomy. There had been no recurrence eight years later.

Case 4. Andrews. This patient was a female, aged 43 years. A small growth on the left iris had been observed for a long time. The tension was elevated but the vision equaled 20_{20} . There was some circum corneal injection but no pain. Enucleation was performed and the growth proved to be a pigmented spindle-celled sarcoma originating in the stroma of the iris.

The canal of Schlemm was somewhat narrowed and surrounded by a collection of the spindle-shaped cells.

Case 5. Buffum. A female, aged 55 years, had noticed a "peculiar appearance" of the right iris for eight years. She had become blind in this eye gradually after repeated attacks of inflammation. The last attack was present three weeks before the examination. Since then the pain had continued. There was an injected bulb and the tension was about +2. In the upper part of the iris there was a cyst like development involving the upper two-thirds. The lower third contained several brownish spots. The aqueous was muddy, the lens hazy and the fundus indistinguishable. The growth was removed by iridectomy. Recurrence took place in three months. Enucleation was then performed. No recurrence had taken place at the expiration of eighteen months. The tumor was a spindle-celled sarcoma. The ciliary body had become secondarily involved.

Case 6. Carter. The patient was a male, age 15 years, who had noticed several small specks on the left iris for three months, and two small specks on the right iris for fourteen days. At the time of the examination there was a yellowish growth half as large as a pea in the lower and inner quadrant of the left iris and small yellowish spots at the margin of the right iris in the external half. There were small circular opaque deposits in the layers of the cornea. The tension was normal and Jaeger I could be read with each eye. Iridectomy was performed in the left eye but the growth recurred. In the right eye the spots were so enlarged nine months after the operation that only large objects could be seen. The tumor was a round-celled sarcoma.

Case 7. Charnley. This patient was a male, aged 16 years. A spot had been observed on the iris eleven years before and there had been occasional attacks of obscuration of vision from hemorrhage into the anterior chamber. At the time of the examination there was found on the lower and inner quadrant of the iris a small brownish gray tumor about one-twentieth of an inch in diameter. Vision equaled 6_{10} . Recently red spots had appeared on its surface. It was removed by iridectomy and proved to be a non-pigmented spindle-celled sarcoma.

Case 8. Collins. A male, aged 21 years, presented himself for the treatment of a brownish growth of the left iris that was situated on the inner and lower quadrant. A photograph of the patient taken four years before the examination showed a brown spot on the lower and outer portion of the iris. At the time of the operation, however, the larger portion of the growth was on the lower and inner quadrant of the iris. Vision equaled 6_{10} and the tension was "full." Enucleation was performed and the growth, which was a pigmented, small round-celled sarcoma, had not recurred in seventeen months.

Case 9. Dreschfeld. A female, aged 53 years, had noticed some trouble with the left iris for two and one-half years. Examination showed a reddish grey tumor about the size of a split pea in the lower part of the iris. The eye was enucleated and the growth, which probably originated from the intermuscular tissue of the iris, was a non-pigmented spindle-celled sarcoma. The patient was under observation for several years, there having been no recurrence when last seen.

Case 10. Edsall. A female, aged 23 years, had observed a small growth on the temporal side of the left iris, midway between the peripheral and pupillary margins about two years before. At the time of the examination the growth was about the size of a split pea covering the pupillary space and of a dark gray color with a smooth surface. The tension was elevated and the vision equaled 20_{30} , through a small hole in the center of the growth. Frequent hemorrhages were observed in the anterior chamber. Although the personal and family histories were negative, mercury and potassium iodid were administered for a time but without any beneficial result. Enucleation was then performed and the growth was a pigmented, small spindle-celled sarcoma.

Case 11. Ewetzky. This patient, a male, aged 38 years, had noticed some trouble with his left eye for two weeks. Examination revealed a growth in the posterior part of the upper half of the iris pushing the iris forward and pressing on the lens. The tension was normal at this time but later became elevated. Vision equaled 10_{70} . As there was a history of syphilis acquired fifteen years before, the patient was treated with mercury, but vision became reduced to the counting of fingers. Enucleation was then performed and the growth proved to be a pigmented round-celled sarcoma.

Case 12. Fano. The patient was a male, aged 19 years, who had a small brownish growth partially filling the anterior chamber of the left eye. There was some injection of the eyeball and slight vascularization of the cornea with hypopyou. Light could not be distinguished. The cornea was perforated. The operation for staphyloma was first performed and a week

later the stump was enucleated. The examination showed small, regular, pigmented cells.

Case 13.—Hirschberg. The patient was a man aged 38 years, who had noticed a dark spot on the iris of the right eye since childhood, but which had been increasing in size for one year. The visual acuity equaled 20_{30} and the tension was normal. At the time of the operation there was a brownish growth occupying the lower two thirds of the anterior chamber that had originated in the lower portion of the iris. Enucleation was performed, and microscopically the growth was a pigmented spindle-celled sarcoma, probably originating from the anterior layers of the iris. There was no recurrence in six months.

Case 14.—Hosch. A male, aged 66 years, had observed a brown spot on his right iris since youth. There was some injection in the lower part of the conjunctiva but no pain. The lower part of the anterior chamber was filled with a light brown growth that was pushing the iris slightly backward, and that extended almost to the center of the pupil. Externally the margin of the tumor was well defined; internally it disappeared into the iris stroma so that no line of demarcation could be made out macroscopically. The tension was normal and the vision, which at first equaled 10_{30} with a Hm. of 2D., at the time of the operation equaled 16_{100} . The bulb was enucleated and the growth, which was 4 millimeters thick and 7 millimeters high, was confined to the iris and microscopically proved to be a pigmented spindle celled sarcoma.

Case 15.—Kipp. A male, aged 36 years, had noticed a spot on the right iris twelve years before. For one month it had been growing very rapidly. At the time of the operation there was a whitish growth that covered a large portion of the pupil. Tension was normal and vision equaled 20_{30} . The growth began in the lower and inner quadrant of the iris. It was excised by iridectomy and proved to be a non-pigmented spindle-celled sarcoma that probably originated in the iris stroma. There was no recurrence in eighteen months.

Case 16.—Knapp. A male, aged 36 years, had a growth occupying about one third of the iris, which was whitish and obstructed the entire pupil when the latter was not dilated. Vision equaled 20_{70} . Iridectomy was performed and there had been no recurrence of the growth at the expiration of a year. The latter was a non-pigmented spindle-celled sarcoma originating in the iris stroma without any definite line of demarcation.

Case 17.—Knapp. A female, aged 35 years, had a blackish growth about as large as a pea, situated in the lower part of the iris that had been present for many years. During the four years preceding the examination there had been attacks of iritis and temporary increase of intra ocular tension. At the time of the examination, however, the tension was normal and the visual acuity equaled 20_{100} . There was some lenticular opacity that was supposed to have been congenital. An iridectomy was performed and the tumor, which proved to be a pigmented spindle celled sarcoma, grew from the iris stroma without any definite line of demarcation. There were two mild attacks of iritis after the operation, but no recurrence of the growth had taken place in three years.

Case 18.—Knapp. A male, aged 22 years, had observed a small speck in his left iris ten years before. Examination showed a yellowish red growth extending from the iris into the anterior chamber, originating in the lower and outer quadrant and studded with red dots and lines. The tension was normal, although temporarily elevated at times, and the vision was 20_{20} . The growth was removed by an iridectomy and proved to be a non-pigmented round-celled sarcoma originating from the iris stroma without any definite boundary line.

Case 19.—Knapp. A female, aged 53 years, had observed a tumor of the upper and outer quadrant of the iris four months before the examination that had been rapidly increasing in size. It was rather reddish and about the size of a cherry stone. The tension was normal and the vision equaled the perception of light. The eye was enucleated and the tumor, a round-celled sarcoma, was found to have originated from the root of the iris near the ciliary processes.

Case 20.—Krülow. A woman, 25 years old, had noticed for more than seven years a small black spot in the upper and outer quadrant of the right iris. The growth filled about one-fourth of the anterior chamber, covered half of the pupillary space and reached to the cornea. There had been some hemorrhages into the anterior chamber but these were always absorbed. Vision equaled 12_{30} (myopia 1_{30}). The tension was normal. Iridectomy was performed for the removal of the growth which was a pigmented sarcoma consisting of spindle and round cells. There was no recurrence in one year.

Case 21.—Lebrun. A female, aged 36 years, had noticed failing vision for three months, during which time some brown-

ish spots about the size of a radish seed were observed near the external periphery of the iris. The eye was blind. After treating for a while with negative results an iridectomy was performed. Inflammatory symptoms were so great, however, that two weeks later enucleation was performed. The growth was a pigmented mixed, round and spindle-celled sarcoma.

Case 22.—Limbourg. This patient was a female, seven and one half years of age, whose vision in the left eye had been much reduced for fourteen days. There was slight epiecleral injection and some fine lymph exudate was observed on the posterior surface of the cornea. The anterior chamber appeared to be deeper than normal. The upper and inner part of the iris was occupied by a small yellowish growth, with a smooth surface that reached to the cornea in front. The tension was elevated and vision equaled the counting of fingers at 1 M. The eyeball was enucleated and the growth proved to be a non-pigmented round-celled sarcoma. The ciliary body and canal of Schlemm had become secondarily involved.

Case 23.—Little. The patient, a female, aged 20 years, gave the history of sudden blindness in the right eye sixteen months before while stooping. This lasted for about one week. On recovering her vision she noticed for the first time a spot on the colored part of the eye. During those sixteen months there had been three or four attacks of dimness of vision at irregular intervals, but after each attack vision had returned. These were presumed to be due to hemorrhage into the anterior chamber. At the time of examination there was a pale brown mass about the size of a small pea in the lower and outer quadrant of the iris that extended from the pupillary margin to the periphery. Vision equaled 20_{20} . The growth was removed by an iridectomy and was found to be a pigmented round-celled sarcoma. There had been no recurrence in twenty-one months.

Case 24.—Oemisch. A female, aged 42 years, had observed six years before a dark spot on the lower and inner quadrant of the iris, from which there were occasionally hemorrhages. During these periods the vision was markedly reduced. After a period of quiescence it began to grow rapidly. In the anterior chamber there was a dark grayish-blue mass that reached nearly to the surface of the cornea and covered a large part of the lower and inner quadrant of the iris. It was about as large as a pea and reached to the pupillary margin. Iritis had been present. Vision equaled 5_{10} . The growth was removed by iridectomy and was a non-pigmented spindle-celled sarcoma. There was no recurrence in four months and the patient had useful vision, being able to read "calendar figures" at 6 M.

Case 25.—Pflüger. The patient was a female, aged 55 years, who had observed a growth on the right iris six years before. It had been gradually increasing in size and there was entire absence of pain. There was a history of malignant disease in the mother originating in the naso-orbital region and extending to the globe of the eye. In the present case the cornea was normal. In the lower outer quadrant of the iris there was a dark brown tumor of irregular contour about 3 by 4 by 5 mm. in size, extending from the periphery of the iris almost to the pupillary margin. Above the horizontal meridian there was a second smaller growth, separated from the other near the pupil by healthy iris tissue, but connected with it near the periphery of the iris. The pupil was round, but with mydriasis there seemed to be posterior synechiae and opacity of the lens and capsule. Vision equaled 5_{15} in each eye. A broad peripheral iridectomy was performed, removing both parts, and there had been no recurrence in two years. The visual acuity remained 5_{15} . The growth was a pigmented spindle-celled sarcoma.

Case 26.—Pflüger. In the same paper the author records a case occurring in the practice of Dr. Horner, the history of which is as follows: A female, 36 years of age, had been aware for ten years of the existence of a small black spot on the lower quadrant of the left iris, that for a short period had been gradually increasing in size. The eyes were not inflamed. The pupil was oval and the growth extended from the margin of the pupil to the angle of the anterior chamber. It was removed by iridectomy and had not recurred at the expiration of three years. The microscopic examination is simply stated to have proved the diagnosis of sarcoma to have been correct.

Case 27.—Quaglino and Guiato. The patient was a female child, aged 6 years, on whose left iris there had been observed a small growth three months before. There was no irritation nor severe pain. Tension equaled +2. The patient could only count fingers, and the mass occupied about two-thirds of the anterior chamber. The parents were perfectly healthy. Enucleation was performed and was followed by a phlegmonous inflammation of the orbit. Microscopic examination showed the growth to be a pigmented round and spindle-celled sarcoma.

Case 28.—Robertson and Knapp. A female, aged 24 years, complained of poor vision in the right eye for one year. Exam-

Number.	Author.	Sex and age.	Eye affected.	First noticed.	Condition at time of operation.	Tension.	Visual acuity.	Primary position of growth in iris.	Operation.	Later history.	Histology.
1.	Adams	F., 13	O. S.	One month before examination.	Brown growth as large as two pins' heads with a smaller one adjoining. Several nodules throughout iris, the largest being in the lower outer quadrant.	At first normal in 2 weeks +	20/50	Lower and outer quad.	Enucleation	Recurrence in 18 months.	Round-celled.
2.	Alt	F., 2	O. D.	One month before examination.	Several nodules throughout iris, the largest being in the lower outer quadrant.	At first normal in 2 weeks +	L. P.	Lower and outer quad.	Enucleation	Recurrence in 18 months.	Round-celled.
3.	Andrews	F., 47	O. S.	Discoloration at site of growth for many years.	Brown growth as large as two pins' heads with a smaller one adjoining. Several nodules throughout iris, the largest being in the lower outer quadrant.	At first normal in 2 weeks +	20/100	Lower and outer quad.	Iridectomy, fol. by supp. in globe necessitating enucleation a week later.	No recurrence in 8 years.	Pigmented spindle-celled.
4.	Andrews	F., 43	O. S.	Small growth observed for a long time.	Cyst-like development occupying upper 2/3 of iris; in the lower part there were several brown spots.	Normal.	20/20	Upper half.	Enucleation	No recurrence in 18 months.	Pigmented spindle-celled.
5.	Buffum	F., 55	O. D.	Had observed "peculiar appearance" of the right iris for 8 years.	O. D., yellow spots on outer half at margin. O. S., yellow growth half as large as pea.	Normal.	Jg. 1; Jg. 1	O. D. outer 1/2. O. S. lower inner quad.	Iridectomy in O. S.	O. S. recurred; O. D. spots so large 9 mos. after operation only large objects seen.	Round-celled.
6.	Carter	M., 15	O. D.	For 3 months small specks on left iris and for 14 days on right iris.	Small growth, one-twentieth inch in diameter, overlapping pupillary margin.	Normal.	6/9	Lower and inner quad.	Iridectomy	No recurrence in 17 months.	Non-pigmented spindle-celled.
7.	Charnley	M., 16	O. S.	Spot on iris noticed 11 years before.	Brown growth	Normal.	6/6	Lower and inner quad.	Enucleation	No recurrence in 17 months.	Pigmented round-celled.
8.	Collins	M., 21	O. S.	Photograph taken 4 years before examination showed spot on the iris. Two and half years before.	Reddish-green growth the size of a split pea in lower part of iris. Smooth, dark gray growth, size of a split pea, covering pupillary space.	Normal.	20/30 through a hole in center	Lower half.	Enucleation	No recurrence in several years.	Non-pigmented spindle-celled.
9.	Dreschfeld	F., 53	O. S.	Two years before.	Growth in posterior part of iris pressing on the lens and pushing iris forward.	Normal.	10/70	Upper half.	Enucleation	No recurrence in several years.	Pigmented small spindle-celled.
10.	Edsall	F., 23	O. S.	Two weeks before.	Injection of bulb; slight vascularization of the cornea and hypopyon; cornea perforated by brownish tumor.	Normal.	0	Lower half.	Enucleation	No recurrence in several years.	Pigmented round-celled.
11.	Ewetsky	M., 38	O. S.	Dark spot in iris since childhood; enlarging 1 year before operation; that does not enlarge.	Brownish growth occupying lower two-thirds of anterior chamber. Light brown growth occupying 2/3 of anterior chamber so that pupil shows only as a small fissure.	Normal.	20/30	Lower half.	Enucleation	No recurrence in several years.	Pigmented spindle-celled.
12.	Fano	M., 19	O. S.	Observed 12 years, growing rapidly 1 month.	Whitish growth covering a large portion of the pupil.	Normal.	20/20	Lower and inner quad.	Iridectomy	No recurrence in several years.	Non-pigmented spindle-celled.
13.	Hirschberg	M., 38	O. D.	Small black spot for seven years.	Whitish growth occupied 1/3 of iris and obstructed pupil when latter was not dilated. For 4 years had been having attacks of iritis with transient elevation of tension.	Normal.	20/70	Lower half.	Iridectomy	No recurrence in 1 year.	Non-pigmented spindle-celled.
14.	Hosch	M., 66	O. D.	For years blackish growth size pea in lower part of iris.	Yellowish red growth extending from iris into anterior chamber and studded with red dots and lines.	Normal.	20/100	Lower and outer quad.	Iridectomy	No recurrence in 3 years.	Pigmented spindle-celled.
15.	Kipp	M., 36	O. D.	Small specks noticed in iris 10 years before.	Reddish growth as large as a cherry stone.	Normal.	20/20	Lower and outer quad.	Iridectomy	No recurrence in several years.	Non-pigmented round-celled.
16.	Knap	F., 53	O. S.	Four months before examination; rapid growth.	Fills 1/4 of anterior chamber, covers half the pupil and reaches to the cornea.	Normal.	L. P.	Upper and outer quad.	Enucleation	No recurrence in 1 year.	Round-celled.
17.	Krukow	F., 25	O. D.	Small black spot for seven years.	Yellowish growth in upper part of iris reaching to the cornea.	Normal.	Myopia, 1/36 12/30 0	Upper and outer quad.	Iridectomy	No recurrence in 21 months.	Pigmented spindle-celled.
18.	Lebrun	F., 36	O. S.	Falling vision for 3 months. Some brown spots external part of iris the size of radial seed.	Pale brown mass as large as a pea extending from margin of pupil to periphery of iris.	Normal.	Counts fingers at 1 N.	Upper and inner quad.	Iridectomy followed by iridectomy, performed 2 weeks later.	No recurrence in 21 months.	Non-pigmented round-celled.
19.	Limbourg	F., 7 1/2	O. S.	Impaired vision 14 days; evidently from hemorrhage in anterior chamber.	Dark grayish-blue mass size of pea reaching nearly to cornea; iritis had existed.	Normal.	20/20	Lower and outer quad.	Iridectomy	No recurrence in 4 months.	Non-pigmented spindle-celled.
20.	Little	F., 20	O. D.	Spot observed on iris after attack of sudden blindness, before exsiccation; several attacks dim vision since.	Dark brown growth connected with a smaller one in outer part of iris.	Normal.	5/9	Lower and inner quad.	Iridectomy	No recurrence in 3 years later.	Pigmented spindle-celled.
21.	Oemisch	F., 42	O. D.	Dark spot observed for six years, frequently bleeds.	Growth extends from margin of pupil to angle of anterior chamber.	Normal.	5/15	Lower and outer quad.	Iridectomy	No recurrence in 3 years.	Pigmented spindle-celled.
22.	Pfuger	F., 55	O. D.	Spot on iris for 6 years; gradually inc. in size.	Two-thirds of the anterior chamber filled by tumor mass.	Normal.	Counts fingers	Upper and outer quad.	Enucleation	No recurrence in 2 years.	Pigmented round-celled with a few spindle-cells.
23.	Pfuger	F., 36	O. S.	For 10 years a small black spot on left iris, increasing slowly in size.	Large brown mass filling external half of anterior chamber, pushing iris backward. The whole iris stroma converted into the tumor mass occupying anterior chamber.	Normal.	6/100 excen.	Upper half.	Enucleation	No recurrence in 3 years.	Pigmented spindle-celled.
24.	Quaglino and Guato	F., 6	O. S.	Small growth observed for 3 months.	Two-thirds of the anterior chamber filled by tumor mass.	Normal.	Counts fingers	Upper and outer quad.	Enucleation	No recurrence in 2 years.	Pigmented round-celled.
25.	Robertson and Knapp	F., 24	O. D.	Poor vision for 1 year.	Two-thirds of the anterior chamber filled by tumor mass.	Normal.	Counts fingers	Upper and outer quad.	Enucleation	No recurrence in 2 years.	Pigmented round-celled.
26.	Romice	F., 74	O. S.	Poor vision for 14 years.	Two-thirds of the anterior chamber filled by tumor mass.	Normal.	6/100 excen.	Upper half.	Enucleation	No recurrence in 3 years.	Pigmented spindle-celled.
27.	St. John	M., 50	O. S.	Black spot observed for one year.	Two-thirds of the anterior chamber filled by tumor mass.	Normal.	6/100 excen.	Upper half.	Enucleation	No recurrence in 3 years.	Pigmented spindle-celled.
28.	Saner	F., 7	O. S.	Four months before examination.	Two-thirds of the anterior chamber filled by tumor mass.	Normal.	6/100 excen.	Upper half.	Enucleation	No recurrence in 3 years.	Pigmented spindle-celled.

tumor showed it to be a pigmented spindle-celled sarcoma. The ciliary body, the spaces of the pectinate ligament, the venous plexus and the equator of the lens were all secondarily involved.

Case 37.—Verter. This patient was a female, aged 60 years, who had observed some weeks before a small dark, cinnamon-colored growth upon the right iris. The media were transparent and the visual acuity equaled $\frac{2}{5}$ with + S 1.50 D. The vision of the left eye was normal with + S 1.50 D. Iridectomy had been advised at the time of first observation of the growth, but at the time consent to the operation was obtained the size was so much increased that enucleation was performed. The tumor was a pigmented spindle-celled sarcoma, and had secondarily involved the ciliary body, Schlemm's canal, Fontana's spaces and the cornea. A small cyst was also found in the periphery of the retina.

Case 38.—Walker. Patient was a female, aged 59 years, who had a cataract extracted from the left eye three years before without iridectomy. For a time before the examination the vision had been failing in this eye. There was no pain or inflammatory symptoms, but inspection showed a pinkish growth filling the pupillary space and strongly resembling secondary cataract. Dissection was performed without benefit, the iris being rotten and adherent to the capsule. Three weeks later the eye was enucleated and the mass found to be a small spindle-celled sarcoma. Before enucleation the growth had extended to the cornea in front, obliterating the anterior chamber and looking very much like a large dislocated lens.

Case 39.—Webster and Van Gieson. The patient was a female, aged 60 years. For four weeks she had seen a "purple mist" before the left eye. There was found a growth about the size of a small pea in the lower and outer quadrant of the iris. The tension was elevated and the vision equaled $\frac{20}{70}$. There was also present anterior polar cataract and edema of the retina. Enucleation was performed and the growth was found to be a pigmented spindle-celled sarcoma.

Case 40.—Werther. A female, aged 72 years, had a brownish-black semiblobular tumor about the size of a hemp-seed, in the lower and outer quadrant of the right iris. Enucleation was performed and the growth was found to be a pigmented spindle-celled sarcoma.

Case 41.—Werther. A female, aged 60 years, had observed a few weeks before a semiblobular, brownish-black tumor of the right iris about the size of a hemp-seed. There was a hypermetropia of 1.50 D., and the vision equaled $\frac{2}{5}$. The growth was situated in the lower and inner quadrant. The eyeball was removed by enucleation and the growth proved to be a spindle-celled sarcoma, part pigmented and part non-pigmented. There was also found a cyst formation in the periphery of the retina.

Case 42.—Whiting. The patient was a male, aged 49 years, who had observed a spot on the left iris since 10 years of age. Several years before he had consulted Dr. Knapp, and at that time the eyeball became occasionally inflamed and there were hemorrhages into the anterior chamber. At the present examination there was a dark brown growth filling the entire lower inner quadrant of the anterior chamber, covering the inferior internal margin of the pupil, which was oblong. There were no synechiae. The cornea was slightly hazy from contact at several points. Vision of the right eye equaled $\frac{20}{20}$; of the left, $\frac{20}{70}$. Nine years later the patient returned on account of severe ocular pain and inflammation of the eyeball, which was now totally blind. The tension was elevated. Enucleation was performed and the growth was a pigmented mixed-celled sarcoma, the round cells predominating. The choroid had become secondarily involved and contained a true bony formation.

The case is exceedingly interesting, as the growth was watched for a long time, being observed at ten years of age, remaining harmless for twenty-five years, slowly growing for thirteen years with occasional attacks of iritis and hemorrhages into the anterior chamber for seven years there being no doubt as to its malignancy. The patient refused earlier operative interference. There had been no recurrence at the expiration of six months.

Case 43.—Wiegmann. The patient was a female, aged 42 years. At birth there was observed a dark tumor about $\frac{2}{5}$ mm. in diameter on the lower and outer quadrant of the iris, that had remained unchanged until seven months before the examination, when it began to enlarge. The tension was normal and vision equaled $\frac{2}{5}$. Iridectomy was performed and was followed nine months later by the application of the galvanocautery to a dark spot in the wound. This was repeated in about two weeks. The tumor was a pigmented spindle-celled sarcoma and no recurrence had been noted at the expiration of one year.

Case 44.—Williamson. This patient was a female, 14 years

of age. Six months before, there had been noticed on the lower and outer quadrant of the left iris a yellowish spot. At the time of the examination the growth reached to the pupillary margin, having begun in the periphery. An attempt was made to remove the tumor by an iridectomy, but this was followed, three days later, by enucleation of the eyeball as the growth was found to be firmly attached by deep adhesions. Microscopic examination showed it to be a non-pigmented spindle celled sarcoma.

Case 45.—Zellweger. A female, aged 75 years, had noticed a small spot on the right iris for a long time. During the six weeks preceding the examination it had been growing very rapidly. There had been no pain or inflammatory symptoms at any time. The examination showed a pale, pinkish, vascular growth in the lower part of the iris, and beginning cataract. The tension was normal and the vision equaled the counting of fingers at $2\frac{1}{2}$ M. The growth was removed by iridectomy and was a non-pigmented small spindle-celled sarcoma originating from the anterior layers of the iris. There was no recurrence *in situ* in six months, but as the patient had some loss of appetite the author questions whether a recurrence had taken place by metastasis. Of this there was no later proof.

Arlt refers to two cases from whom the growth was removed by iridectomy, and to a third case requiring enucleation of the eyeball. In neither were there any details of the histories, either prior or subsequent to the operations.

Fuchs, in the discussion of a paper, refers to a case of primary sarcoma of the iris for which the eyeball was enucleated, but the details of the history are too meager to be of any use.

Cases in which primary sarcoma of the iris was diagnosed but which were not operated upon, are recorded by Berthold, Fuchs, Galezowski, von Graefe, Hasner, Owen, Pflüger, Saltzmann, St. John Roosa and Stober.

In order that the cases may be more easily analyzed, and to facilitate reference to any particular point in connection with them the accompanying table has been prepared somewhat after the manner of Fuchs. It will be seen therefore from the above that there have been recorded forty-six cases of primary sarcomata of the iris in which operative procedures have been undertaken and microscopic examinations made. Of these cases we have fourteen males, thirty-two females, giving, in round numbers, 69.5 per cent. of females and 30.5 per cent. of males.

The ages range as follows: From 1 to 5 years, one case; from 6 to 15 years, six cases; from 16 to 25 years, nine cases; from 26 to 35 years, 1 case; from 36 to 45 years, ten cases; from 46 to 55 years, nine cases; from 56 to 65 years, five cases; 66 to 75 years, five cases.¹

By referring to the above it will be seen that between the ages of 15 and 25 inclusive there occurred ten cases, and between 35 and 45 inclusive there occurred eleven cases, whereas the intervening period, from 25 to 35, contained only one case. There seem, therefore, to be two periods during which the disease is most likely to manifest itself, viz., between the ages of 15 and 25 and between the ages of 35 and 45, with a very moderate increase of predisposition in favor of the latter period, the intervening period, that is from 25 to 35 being almost free from the affection, as only

¹ If instead of analyzing the ages according to decades, we take 5-year periods, the age of predisposition can be reduced even further, still conforming with the statistics of the above tables. From 1 to 5 years, one case; from 6 to 10 years, three cases; from 11 to 15 years, three cases; from 16 to 20 years three cases; from 21 to 25 years, six cases; from 26 to 30 years, no cases; from 31 to 35 years, one case; from 36 to 40 years, six cases; from 41 to 45 years, four cases; from 46 to 50 years, four cases; from 51 to 55 years, five cases; from 56 to 60 years, four cases; from 61 to 65 years, one case; from 66 to 70 years, one case; from 71 to 75 years, four cases. It will be seen, therefore, according to this, that from 20 to 25 and from 35 to 40 years of age afford the periods of greatest predisposition. This result entirely agrees with that obtained from the first table, the former, perhaps, being slightly more accurate as it affords a greater range.

one of the forty-six cases occurred during this time. Beyond the age of 45 the predisposition decreases very gradually and *vice versa*, the nearer we approach this age the greater becomes this predisposition.

It must be considered, however, that the above figures represent in many cases the ages at which the patients were operated upon. But as the greater number of cases were operated upon shortly after coming under the observation of the various authors, and as most of them came under observation shortly after the growths in the iris were discovered, the two periods given represent quite fairly the decades of greatest predisposition.

The youngest case in the list was 2 years of age and the oldest 75 years of age, the average age being 39.3 years.

It is to be noted also that seventeen of the cases occurred before the 35th year and twenty-nine after the 35th year; or, if the 40th year be taken as the dividing line we have an equal number on either side, namely, twenty-three.

As to the ages when the growths were first observed to be in an active state, it is impossible to give any definite statistics. The larger number of patients consulted surgeons within a short time after the discovery of the affection, but it must be remembered that many of the growths have the history of originating from apparently dark tumors of the iris, melanomata, which after remaining in a state of quiescence for many years assumed a malignancy that microscopic examinations afterward proved to be sarcomata.

We find that the left eye has been more frequently affected, though the difference in predisposition is not marked, the actual ratio being as follows: Right eye affected in nineteen cases; left eye affected in twenty-one cases; both eyes affected in one case; not stated in five cases.

The tension as given in the histories is as follows: Normal in eleven cases; elevated in sixteen cases; not stated in nineteen cases.

In five of the cases given as "elevated" the histories state that the tension was normal as a rule, but at times elevated. Thus of those cases in which the condition of the tension is recorded we have 40.7 per cent. normal, 40.7 per cent. elevated and 18.6 per cent. as varying, being sometimes normal and sometimes elevated. This differs somewhat from the recently published statistics of Devreaux Marshall, who has found in intra-ocular neoplasms affecting the iris or ciliary body that the tension is increased in 35.71 per cent. diminished in 14.28 per cent. and normal in 50 per cent. As his cases were not, however, exclusively primary growths of the iris, but growths affecting either the ciliary body or the iris, or both, being primary and secondary, the difference may be easily accounted for. In no one of the cases of primary sarcomata of the iris was the tension stated to have been diminished.

The condition of the visual acuity in these cases ranged thus: Normal in nine cases; 20/100, or better, in fourteen cases; less than 20/100 in eight cases; light perception in two cases; blind in six cases; not stated in eight cases.

In some of the cases the lens was more or less cataractous (Alt's, Knapp's, Oemisch's, Verter's and my own). In the latter case, after the extraction of the lens the patient obtained vision equal to 5/6 and easily read Jaeger 1.

The positions occupied by the tumors on the surfaces of the irides are variously given as follows: Lower and

inner quadrant, seven cases; lower and outer quadrant, eleven cases; upper and inner quadrant, three cases; upper and outer quadrant, three cases; lower half, five cases; upper half, three cases; outer half, two cases; not stated, thirteen cases.

Of the thirty-two definitely stated cases we have, therefore, twenty-three cases, or 71.8 per cent. originating from the lower half of the iris, and nine cases, or 28.2 per cent. originating from the upper half of the iris. There seems also to be a somewhat greater predisposition to occur in the outer portion of the lower half, or in the lower outer quadrant of the iris.

The operations that were performed in the recorded cases were: Enucleation in thirty-two cases; iridectomy in fourteen cases. In the above thirty-two cases under the heading "enucleation" are included four cases in which iridectomy was first performed and in which enucleation was subsequently required. In Andrews' case, enucleation was performed a week after the iridectomy, because of suppuration of the globe; in Lebrun's case it was performed two weeks later because of "inflammatory symptoms" in the globe; in Williamson's case three days later, because the iridectomy disclosed the fact that the growth was attached by "deep adhesions;" in Buffum's case three months later, because of recurrence. In Carter's case the growth recurred, but it was so distinctly unfavorable that nothing else could have been expected. So that we have out of forty-six cases operated upon, the successful removal of the growth in thirteen cases, by iridectomies, in which no recurrence is recorded during the time they remained under observation, which varied from four months to many years. In none of the enucleations are recurrences positively recorded, but in one (Zellweger's case) a loss of appetite with some gastro-intestinal disturbance was looked upon as probably the beginning of a metastatic process, though no subsequent mention is made of it.

The histologic examinations of the growths showed that twenty-seven were pigmented, ten cases were non-pigmented, and nine cases not definitely stated.

It seems somewhat odd that in a tissue so highly pigmented as the iris we should have a non-pigmented growth, yet in the thirty-seven cases definitely recorded we have in round numbers 27 per cent. of the non-pigmented variety and 73 per cent. of the pigmented variety.

As to the cellular formation of the growths we have twenty-three cases of spindle celled; eleven cases of round celled; seven cases of mixed celled; five cases not definitely stated.

This, in round numbers, places in the spindle celled classification 56 per cent.; in the round celled classification 27 per cent., and in the mixed celled classification 17 per cent. of the reported cases.

Symptoms.—From a study of the recorded cases it is seen that primary sarcoma of the iris may occur at almost any age, the youngest being 2 years, the eldest 75 years of age, the periods of greatest predisposition being between the 15th and the 25th, and between the 35th and the 45th years. As a rule it is first observed as a spot of discoloration upon the iris, which, after a period of quiescence varying from a few weeks to many years, begins to increase rapidly in size, interfering with vision according to the degree of inflammation it has caused and the amount of pupillary space covered. Vision is also sometimes obscured for short periods of time by transient increase of the intra-ocular tension or by hemorrhages from the growth

into the anterior chamber. Sooner or later it is apt to produce iritis and by pressure backward to cause opacity of the capsule and lens. Tension is presumably increased when the growth attains sufficient size, or has brought about sufficiently violent inflammation to interfere with the interchange of the ocular fluids. If left to itself it attains considerable size, perforating the external coats of the eye, and usually produces blindness. It occurs twice as frequently in females as in males, each eye seems to be equally predisposed and the favorite position seems to be in the lower half, and especially in the lower and outer quadrant of the iris.

Diagnosis.—Primary sarcoma of the iris may be mistaken for simple melanoma, for gumma, or for primary tubercle of the iris.

A simple melanoma becomes darker and darker while a melano-sarcoma ordinarily retains its primary shade. A melanoma is also a congenital growth while sarcoma is not. If the patient, or patient's family, can give no accurate information on this point the growth must be watched for some time to note if there is any progress (Fuchs).

Whenever a gumma of the iris appears there is a severe iritis, whereas in the early stage of sarcoma of the iris there are no inflammatory symptoms. In gumma of the iris, also, there is a specific history with other symptoms referable to syphilitic infection.

The color of the gumma is either an iron-red or deep yellowish-red, while that of sarcoma is reddish-gray, blackish or light brown, or flesh-color (Andrews.) Gumma is non-vascular and yellowish-white in color at the summit, but at the base it is vascular and has a yellowish-red border (Fuchs). If the diagnosis can not be positively made from the examination, the administration of anti-syphilitic remedies, for a short time, in large doses will clear up the matter.

Tubercle of the iris is of much more rapid growth than sarcoma and in color is of a light yellowish-white, or light grayish-white, or light grayish yellow (Andrews). As a rule no vessels are seen on its surface, whereas in sarcoma superficial vascularization can usually be detected. The larger number of cases of tubercle have occurred in subjects under 15 years of age, whereas the larger number of cases of sarcoma have been found in older persons. Tubercle is much more irregular in form than sarcoma and the accompanying inflammatory symptoms also appear earlier.

Treatment.—If the growth is sufficiently small and does not extend to the extreme ciliary portion of the iris an attempt should be made to remove it by an extremely broad peripheral iridectomy. The statistics conclusively prove that in many cases not only has the eyeball been preserved but with useful vision, and that no recurrence has been noted years after the removal of the growth by this operation. If the growth, however, is so large or is situated so near the ciliary margin of the iris that it is impossible to remove all of it by an iridectomy, or if any other portion of the eye has become secondarily involved, immediate enucleation should be performed.

DISCUSSION.

Dr. HOWARD F. HANSELL of Philadelphia.—My remarks on

this interesting addition to the literature of primary sarcoma of the iris concern chiefly the differential diagnosis between this and other forms of tumor of the iris and ciliary body as I have had opportunity to observe them in my practice. These affections, with the exception of tumors of syphilitic origin, are among the rarest of eye diseases and it is only by a collation of individual experiences rather than by the classic and oft repeated dicta of any one writer that advance may be made in our knowledge. Until very recently I believe it was the common impression that sarcoma of the uveal tract was a distinctly fatal disease, but the paper of Mathews and the discussion that followed it showed conclusively that in many cases it was years before enucleation was necessary. The slowness of growth may be attributed to the serous sac that in cavities that have serous linings, forms over the tumor and prevents involvement and disintegration of neighboring structures. Eventually this envelope becomes attenuated to such a degree that it is no longer able to sustain the pressure from within and, rupturing, the sarcoma cells find new soil for development. Two cases exhibited this winter by Carpenter and Perrine, before the Section on Ophthalmology of the College of Physicians of Philadelphia, had been of extremely slow growth and enucleation was finally resorted to in order to relieve the pain of secondary glaucoma rather than because the tumors showed a tendency to spread. Identical grounds for treatment prevail when the tumor is recognized as belonging to the so-called benign variety, and we may therefore infer that primary sarcoma of the uveal tract is *per se* not an especially malignant affection.

The diseases that most closely resemble sarcoma of the iris are fibroma, cyst, gumma and primary tuberculosis; yet in none of these should the diagnosis long remain uncertain, particularly after operative interference. Considered clinically only, a fibroma offers the following points of difference: It occurs as a rule in young patients as the result of traumatism, and is not a result of inflammatory exudation although it often gives rise to inflammation; the color is that of the iris stroma or darker; it is oblong in shape and shows a tendency to extend by increase in the area of its base and not by layers of deposit; its surface is rough, presenting a strong contrast to the smooth encapsulated shining surface of the sarcoma. It is non-vascular except when the associated iritis is of high grade; exacerbations of iritis are common, hence posterior synechiae, not limited to the site of the tumor although secondary to it, are numerous. Vision is interfered with according to the situation, size, rate of growth and the degree of transparency of the anterior capsule. Family history in the cases I have seen did not enter into a consideration of the diagnosis. In sarcoma there is perhaps a family history of tumor, the patients have reached middle age; the outline is sharp and well defined, the surface is smooth and shiny to oblique illumination and its form round and, if old, nodulated; the pupil dilates irregularly, the non-involved portion of the iris dilating to light and mydriatics while the portion adjacent to the tumor is adherent to the anterior capsule.

In cyst a history of traumatism can invariably be elicited; the tumor grows rapidly, soon coming into contact with the cornea anteriorly and dislocating the lens posteriorly; there is no iritis and but little interference with vision until adjoining parts are disturbed in their function; it is pearl color, non-vascular and painless, its outer limiting membrane is fibrous and its inner is serous in its nature; its contents is straw-colored, nearly transparent and semi-fluid. Thus in nearly every essential it differs from sarcoma.

Gumma is always associated with and causatively related to the iritis of secondary or tertiary syphilis. In color, in intensity of inflammation, in the presence of hypopyon or collections of broken-off necrosed masses of the tumor in the anterior chamber, in the severity and character of the pain, in the loss of vision and in the history, it offers few points of resemblance to sarcoma. In primary tuberculosis the iris is dotted in numerous places with small deposits, averaging the size of a pin's head, of somewhat lighter color than the healthy iris tissue. In the only case that has fallen under my observation it appeared in the early childhood of the offspring of a tuberculous parent. The vision was reduced to the perception of light, and there were no signs of inflammation.

One point of interest common to all cases of tumor either of the iris or other tissues of the eye, may be mentioned. I refer to the intra ocular tension. I have found tension to be unaltered until the late stages, when I have regarded the increased pressure to be the result of secondary glaucoma and not to an increase in the contents or to a change in their character but to a disturbance of the relation between secretion and excretion. If perforation of the coats of the ball has taken place, high will naturally be succeeded by low tension and such a succession would indicate an advance in the growth.

A DUCTION INDICATOR AND PHOROMETER COMBINED.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY A. E. PRINCE, M.D., PH.D.

SPRINGFIELD, ILL.

In 1892 I conceived the idea of simplifying the determination of the static relation of the optic axes by placing a Maddox rod behind two rotating prisms, thus avoiding the necessity of employing a series of prisms, and presented this conception in a paper read before the Ophthalmological Section of the AMERICAN MEDICAL ASSOCIATION, at Detroit. In 1893 this idea was embodied in my phorometer published in the *Archives of Ophthalmology*. This conception has been adopted by Wilson in the construction of his instrument. The dial is so graduated as to indicate the combined effect of the two prisms in every possible relation to one another, and each quadrant of the dial is lettered to indicate the character of heterophoria. In testing for hyperphoria, the index will point to R.H., L.H., or 0, denoting the degree of right or left hyperphoria, or the existence of neither. Similarly in observations relative to esophoria or ex-

ophoria, the index will point to Ex., Es., or 0, denoting the degree of exophoria, esophoria or the absence of either of these conditions.

Prompted by the successful operation of this instrument in determining the static relation of the recti muscles, Bonschur & Holmes in 1894 made, at my suggestion, an instrument for determining the dynamic capacity of the recti muscles. The prism employed had a strength of seven and a half degrees, thus furnishing every possible prism from 0 to 15 degrees. The graduated quadrants were lettered respectively Ad., Ab., R. S., and L. S., to indicate adduction, abduction, right sursumduction and left sursumduction. This instrument was presented to the profession through the *Ophthalmic Record*, July 1894, under the title of "A Duction Indicator and Developer."

The third step in the evolution is the use of a Maddox multiple red rod in place of a single rod, thus avoiding the necessity of centering the instrument

before the eye, which was the case with the original phorometer.

The fourth step in the evolution completes the instrument which I offer you today. It consists of two seven and a half degree prisms mounted in a circular metal frame and caused to rotate in reverse directions; in this manner every possible degree may be obtained.

The direction of the base of the resultant prism is always in a line transverse to the diameter joining the two zero points, and the strength is always indicated on the margin of the frames opposite the middle point of the base of the prism. Behind this variable prism is placed a Maddox multiple red rod, the axis of which is transverse to the diameter joining the zero points.

In testing the relation of the recti muscles, the instrument is first used as a phorometer, for by so doing the static (or rest) condition may be obtained before any spasm shall have been induced by the requirement of the muscles to overcome prisms.

In testing exophoria and esophoria the instrument is held by the observer, before the right eye and rods, horizontal dial out, and the patient is directed to look at a candle flame placed on a level with the eye and before a dark background. The pinion is then rotated until the vertical red image of light is seen superimposed over the candle flame. The quadrant occupied by the base of the prism will indicate either esophoria or exophoria, and at the point where the middle of the base of the prism cuts the quadrant will be found the degree of heterophoria.

The rods are then rotated into the vertical position when the red streak will be seen in the horizontal plane; when this is brought in line with the flame the amount and character of the hyperphoria when it exists will be indicated on the quadrants corresponding to hyperphoria.

Having ascertained the relation of the optical axes in a state of rest the efficiency of the various muscles to overcome prisms is ascertained by converting the instrument into a duction indicator and proceeding as follows: The multiple red rod having been removed the instrument is held before the right eye as before. The diameter corresponding to the zero points occupy the vertical plane in testing adduction and abduction; the horizontal plane in testing right and left sursumduction. The pinion is rotated until diplopia results, when the amount of prism deviation is read off on the corresponding quadrant indicated by Ad., Ab., R.S. or L.S. In testing R. and L. S. and abduction the prismatic amplitude being fifteen degrees it is usually sufficient, but in testing adduction an auxiliary prism is required.

Auxiliary prisms may be placed in a trial frame, but to economize time and avoid any possible obliquity of the axis, I place before the eyes an ordinary frame in which is mounted two ten-degree prisms base out. The duction indicator will now have an amplitude of from five to thirty-five degrees depending on whether the action of the variable prism acts in conjunction or opposite to the stationary prisms.

The duction indicator and phorometer, as I present it to you today, has been in daily use during the past three years, and I have made numerous comparisons between it and Gould's prism battery, both for determining maximum abduction and adduction, as well as cultivating the capacity of the muscles to overcome prisms of a greater and greater strength, and almost invariably the duction indicator has shown a superi-

ority over the prism battery. This superiority is due to the fact that the increment of increase is infinitesimal, while the increment of increase with Gould's prism battery is two degrees, e. g., in ascertaining the maximum adduction, the patient gets to a point where the overcoming of two degrees in the ascending series is more than the muscles will accomplish, and diplopia, therefore, results. In the use of the duction indicator, turning the pinion slowly, a fraction of a degree is all the muscles are obliged to overcome, and the patient is gradually enabled to exercise the muscles to a greater extent before diplopia asserts itself. In the effort, therefore, to obtain a maximum capacity of the recti muscles in their effort to overcome prisms, the duction indicator is undoubtedly an instrument far superior to any prism battery.

A CLINICAL STUDY OF HYPERPHORIA.

BY JOHN T. CARPENTER, JR., M.D.

Read in the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

PHILADELPHIA, PA.

The importance of recognizing and correcting with absolute accuracy, any existing error of refraction, has long since become an axiom, a truth too evident to require demonstration. In the past decade, mainly as a result of careful clinical study, errors of muscular balance have been attracting the attention of the ophthalmic surgeon; but in this field there still exist wide differences of opinion both as to the importance of muscular defects and the necessity for their treatment. One may find almost anything desired by searching the literature of this subject. If he be naturally conservative he may read of that wonderful and unfailing "cure-all" for muscular imbalance, prismatic exercise. The method of cure is both simple in its application and positively harmless. It is even monotonous in the uniformity of its good results. On the other hand, should the ophthalmologist be surgically inclined; should his desire be to refute the base insinuation that he is a mere "fitter of glasses;" he can find enthusiastic advocates of a measure apparently no less magic in its results, tenotomy of the ocular muscles. There is discord in regard to the prescribing of prisms in the position of rest, a procedure which according to some will transform orthophoria into heterophoria, and increase the amount of heterophoria already existing. Certainly there is need of a more satisfactory presentation of this entire subject of muscular abnormalities, and in passing I wish to mention the excellent work done in this direction by Duane whose valuable contributions in the *Annals of Ophthalmology* (Vols. v and vi), deserve the highest commendation. Risley has put himself on record as an advocate of a more scientific classification of motor anomalies (*University Medical Magazine*, January, 1895).

Hyperphoria is not rare, if by it we mean the tending of one visual axis above that of its fellow. From my case-books I find it in about 35 per cent. of my cases, as discovered by the Maddox rod at the first visit. By no means all of these are true hyperphoria or demand treatment. In these are included cases of hyperphoria combined with esophoria or exophoria as well as those which may justly be termed spurious hyperphoria dependent upon disturbed refractive or muscular conditions and disappearing after these have

been corrected. I have notes of cases in which a change made in the axis of the cylinders in astigmatism resulted in the disappearance of the hyperphoria. (Such cases have also been seen by Risley, *loc. cit.*) I have attributed this kind of hyperphoria to the spasm of the oblique muscles set up by the false position of the cylinder. Spasm of the obliques might readily cause hyperphoria, especially when of variable nature or degree. In these cases prisms in position of rest only aggravate the conditions and result in gradual increase in the amount of the vertical error.

It is important to remember that besides the mere existence of muscular anomalies we must consider their relation to other local ocular states, refractive and accommodative, as well as to general systemic conditions. It is a matter of clinical observation that gouty or rheumatic muscles can closely simulate the clinical picture of heterophoria, and many errors in treatment, notably surgical treatment, are caused by too little regard for this fact. Our efforts should be directed toward the study and arrangement of this subject into definite clinical groups, having a similar causative relation and, therefore demanding a similar and definite line of treatment. It is the lack of this which has brought discredit upon tenotomy as a method of treatment, and much of the uncertainty in, and many of the apparently contradictory results of, tenotomy would be avoided were the anatomic and physiologic questions involved more carefully and accurately studied.

Classification.—For teaching purposes and as an aid to the clinical study of hyperphoria I have adopted the following classification, which though by no means perfect possesses to my mind distinct practical advantages. It avoids the confusion arising from a merely symptomatic arrangement in which cases widely dissimilar in nature are yet grouped together because they reveal a similar tendency to divergence, convergence or vertical deviation.

1. Spurious Hyperphoria. Including:

A. Hyperphoria due to a general disease: gout, rheumatism.

B. Hyperphoria appearing in disease of central nervous system.

C. Hyperphoria secondary to abnormal refractive or muscular states.

2. True Hyperphoria. Including:

A. Concomitant.

B. Spasmodic.

C. Paretic.

Symptoms of hyperphoria include local or ocular, and remote or general symptoms. My case-books show among the ocular disturbances due to hyperphoria:

1. Affections of the lids. The most characteristic is chronic palpebral hyperemia or inflammation, with intense burning pain, as in the "hot eye" of gout and blepharitis; recurring attacks of hordeoli or chalazia, usually in the eye in which the muscle is at fault, seem to be truthfully attributable to hyperphoria, as they have in several cases been cured by correction of the hyperphoria by prism or operation.

2. Reflex ocular neuroses, e.g., epiphora of a very annoying character, photophobia. In one case a quite marked ptosis of the left eye with hyperphoria of 5 degrees almost entirely disappeared after correcting the hyperphoria.

3. Visual disturbance: Amblyopia of the hyperphoric eye (Stevens); transient diplopia which to my mind accounts for most of the inability to carry on

work at a near point; ocular vertigo sometimes severe enough to simulate intra-cranial disease.

4. Muscular asthenopia due to defects in the lateral muscles resulting from effort to correct the vertical error.

The remote symptoms include: Severe headaches made worse by close work; general reflex derangements of the nervous system often most remote from the ocular seat of trouble; nausea and various symptoms whose disappearance after correction of the hyperphoria leads the clinician to infer that they were caused by the muscular defect. No justification exists for the treatment of hyperphoria from which the patient suffers no discomfort and of whose existence he is "sublimely unconscious."

Tests for the determination of hyperphoria.—I find the optometer and phorometer devised by Risley, with two rotary prisms, one fixed for the vertical and the other for lateral muscles, the most satisfactory form of apparatus. I should certainly hesitate to accept results gained by the use of the ordinary trial-frame and prisms in *approximately* accurate positions. The familiar test with the Maddox rod and small point of light reveals any tendency to hyperphoria in most cases. I wish to lay particular stress upon the value of the plane red glass placed before one eye, which gives many valuable hints as to binocular vision, its existence and the conditions under which enjoyed. The cover test slightly modified by allowing the covered eye to be excluded from the binocular vision for some moments will, in hyperphoria give blurred distant vision or even vertical diplopia for the smaller letters, which diplopia is always indicative of the nature and character of the hyperphoria. The value of the field of fixation and the tropometer of Stevens is certainly great in enabling the surgeon to arrive at a complete understanding of the conditions present in the neuromuscular system of the eyes. Having ascertained the existence of hyperphoria it is necessary to determine its true nature. Just as we refer departures from the standard refractive condition, emmetropia, to that ideal so must we have a standard for cases of muscular anomalies. I feel sure that standard as regards the vertical muscles is a condition of equilibrium at 6 m. as revealed by the tests herein enumerated. The vertical muscles should in health be able to overcome the diplopia caused by 2°–4° prism held vertically. Normal muscular balance certainly means a condition of tension of the extra-ocular muscles with power to bring both visual axes promptly into line on the object viewed. Defects of refraction with their compensatory accommodative and muscular efforts must be eliminated by a careful measurement under a cycloplegic and the correction by properly ground and accurately centered lenses made of all important defects, which in my judgment include small amounts of astigmatism. It is important to decide whether the hyperphoria is produced by a general or local cause; neurasthenia, lowered vitality during convalescence from an illness or surgical shock; gouty or rheumatic inflammatory attacks of ocular muscles, and lastly the involvement of the cranial nerves supplying ocular muscles as part of central nervous disease must all be carefully considered in deciding this question.

Neurasthenia with lowered nervous and muscular tone is shown by inability on the part of various muscle groups to overcome the normal prism degree. Insufficiency of convergence is particularly indicative of this trouble. Other symptoms of gout or rheumatism;

dull aching in the eyeballs; congested condition of the ocular and palpebral conjunctiva help one in arriving at definite conclusions as to the gouty or rheumatic origin.

A knowledge of general nervous disease is absolutely essential to the ophthalmic surgeon.

Local causes are best grouped, as Duane has done, into those resulting from overaction and those from underaction, hyper- and hypo-kinesis. In the first class we must place anatomic defects causing true concomitant hyperphoria and also spasmodic hyperphoria from efforts to compensate for a weak or paretic muscle. In the second class are defects varying from simple weakness to absolute paresis of a muscle.

In this connection I should like to emphasize the importance of carefully taking the field of fixation, which should show $35-38^\circ$ upward and $50-55^\circ$ downward rotation. Of equal import is the use of a red glass at 6 m. and a small fixation object-type or small dots, with which diplopia should be sought for in all parts of the field. An increase in the amount of separation in any definite direction leads of course to the belief that the muscle or muscles whose function it is to carry the eye in that direction are weak or paretic.

Treatment.—The therapeutic measures applicable to hyperphoria include local and general measures. Local: Corrective refractive prisms in position of rest; prismatic exercise; operative measures; tenotomy and advancement or muscle shortening. General treatment: Therapeutic measure indicated by the underlying cause. In many cases, painstaking, accurate measurement and correction of the refractive error results in disappearance of the hyperphoria; attention to refractive errors is always the first proceeding. Prisms in position of rest give the greatest relief to some cases, while in other instances only aggravate the discomfort of the patient. Probably the cases in which they give marked and lasting relief are those of long standing and practically stationary paresis of one or more of the vertical muscles. Temporary relief, often very prompt and astonishing, may be gained by hooking on a prism in front of the refractive correction. The relief to remote symptoms by the procedure (at times little short of wonderful) indicates that operative measures will prove equally gratifying in their results. In many cases the result can not be foretold and the practice of allowing patients to wear prisms temporarily, so made as to hook on top of the glass, is one which I can thoroughly commend.

Operative treatment is not applicable in hyperphoria of variable degree; in paretic cases where there is some central nervous disease or where the condition is recent and progressive. Cases of hyperphoria dependent upon a disease of the muscles, rheumatic or gouty occurring in patients well on toward 50 years of age, who have not possessed binocular vision for some years, are also unfavorable for operative procedures.

Tenotomy is perfectly satisfactory and often brilliant in results when the hyperphoria is of the concomitant variety and where it is constant in amount and character, where prism tests and fixation field and other methods show marked overaction of one of the vertical muscles.

Advancement should be preferred to tenotomy in cases of long standing and non-progressive paresis of a vertical muscle, and also where prism tests or fixation field show manifest weakness of the vertical muscles.

In hyperphoria of 1 to 2° and rarely of 0.5° , I have had unexpectedly brilliant results from both prismatic and operative treatment and we should always bear in mind the relatively great disturbance of 0.5° to 1° of hyperphoria when the total strength of the vertical muscles is represented by 2.5° to 3° prism.

My experience with prismatic exercises for the vertical muscles has shown that immediately after tenotomies, where the effect gained has been insufficient, a persistent and faithful course of prismatic exercises, carried on while the conditions of healing are as yet unsettled, results in marked benefit, which I have found to be permanent in its effect.

CONCLUSIONS.

1. It is essential at the outset that a distinction should be made between true and spurious hyperphoria.

2. It is absolutely imperative that before deciding upon any line of treatment for hyperphoria a careful and accurate examination of existing anatomic conditions should be made, which should include: Estimation of refraction, determination of tension of extra-ocular muscles as indicated by their ability to overcome diplopia produced by prisms properly placed; measurement of the field of fixation, monocular and binocular, and an employment of all the tests which tend to remove the strong impulse to binocular single vision and reveal latent defects such as the red glass, Maddox rod, etc.

3. Treatment should be directed against the underlying cause after determination whether the defect be due to spasm, paresis or actual overaction from anatomic conditions, tendon insertion, etc.

4. Tenotomy is indicated only in muscles showing too great power. Advancement or muscle shortening in cases revealing weakness of a muscle or at least no overwhelming power in its antagonist.

5. There is urgent need of a more satisfactory classification of the entire subject of motor abnormalities.

DISCUSSION ON PAPERS OF DRS. PRINCE AND CARPENTER.

Dr. EDWARD JACKSON of Philadelphia—I have not seen Dr. Prince's instrument until now, so I can not give results of any trial of it. I notice one thing in the mechanical execution, that is, the rods are made very perfectly. You can not take half rods for this purpose without getting a slight interval separating the parts of the streak that each rod gives. This has been made by taking a little less than one-half of each rod. The principles involved are not new, but the method of working them out is, and it seems a very simple and efficient instrument.

In noting down the results of such examinations, for several years I have employed certain signs that require less time to write them, less room in the case book, and can be read more quickly and more unmistakably than other abbreviations indicating orthophoria or heterophoria of any kind. Some of them have been employed by others and some, I think, are new. They include the sign of libra (\neg) for lateral balance, and vertical parallel lines (\parallel) to indicate vertical balance. For exophoria the lines diverge from left to right thus $<$, and for esophoria they converge from left to right thus $>$. For right hyperphoria I take the two lines, which for vertical balance are both vertical, and simply place the right line sloping away from the other, thus \vee ; in left hyperphoria, in the opposite direction \wedge . These lines can be read very easily and you can record a half dozen observations, made at different times, on the same line of the case book.

As regards this instrument, the only thing I have to remark is on the extent of the scale, running up to 15 degrees. That is considerable less than rotary prisms have usually been made to give, but will answer all practical purposes. There are many persons with good rotation who do not get more than 15 degrees of adduction on the first trial. If one finds with this that there are 15 prism degrees of adduction, unless there be something pointing to weakness of adduction, this may be assumed in a routine examination to be enough. The weaker the prism, of

course, the more accurate its work for the lower degrees. Still I think this is not equal to the triple rotary prisms which I proposed, which give the long spaces instead of the short spaces between the low degrees. The Maddox rod, in some form, I rely upon chiefly for routine examination for heterophoria. I use it in all cases, and if there is reason to follow out that line of investigation further, I afterward resort to other tests of muscular balance.

Dr. H. M. STARKEY of Chicago—I used the new instrument of Dr. Prince for a short time, it having been sent to me for study, but not long enough to give any definite idea as to whether I should consider it more useful than other instruments we have. I made, in my mind, the same criticism that Dr. Jackson has spoken of, that it would be more easily used if arranged as Dr. Jackson's adduction prisms are. One point in exercising the adductors; if we use the prisms and find adduction of 10, 15 or 25 degrees, we can then place the duction indicator over that and rotate it to the same extent of 15 degrees and the image would still be kept single. If we put a prism of 20 degrees in front of the eyes for stimulating adduction and placing the Prince thorometer in front of that, rotate it until we add 15 degrees, we can not afterward go up to 15 degrees with the prisms; it did not stimulate the muscles except in just that way.

Dr. S. D. RISLEY of Philadelphia—I have been very much interested in this very ingenious instrument and will take an early opportunity to study it more carefully. This is the first I have seen of it in its latest form. I wish to speak particularly of Dr. Carpenter's paper, and to say that I am thoroughly in accord with the principles of classification and the methods of examinations to which he has so briefly but clearly referred. I was glad to see him separate those cases that may be due to general dyscrasia. I am sure these may be readily overlooked. There are many persons with rheumatic or gouty diatheses that have transient spells where the amount of variation in the ocular balance is very irregular. We have all seen transient palsy due to gouty disturbance, and before we enter upon operative procedures these cases should be excluded. One class of cases that were not mentioned is the group where abnormalities are simulated by disease at the macula. I have seen cases in which the eyes were drawn this way or that to get rid of an absolute scotoma. If the Maddox rod is used and you guide the patient a little, you will find a blurred spot in the line itself, or that a section of the rod is absolutely cut out by the blind spot of the macula. I presented a paper at Edinburgh in which I divided these into two classes, 1, those due to some anatomic defect in the muscle or its relation to the ball or to disease, leading to muscular anomalies, and 2, those due to errors of refraction. The last were relative and disappeared when the refractive error was corrected or with brief training of the muscles. The patient had to be taught to overcome the relation between convergence and accommodation.

In this group the correcting glasses make it necessary for him to learn a new order of things as regards the relation between accommodation and convergence, but when he has learned this the relative insufficiencies disappear. I am sure that heterophoria often exists in consequence of anatomic defects in the skull. We know perfectly well that the skull is distorted in a large number of persons. The first group, or the absolute insufficiencies frequently grow out of these abnormalities in the skull and shape of the orbit, which give rise to disturbances in the length of the muscles and their attachments to the eyeball, and in those cases we may correct the error of refraction, but the abnormality of balance will remain until we have adopted some form of operative interference. These I have called absolute insufficiency.

Dr. J. T. CARPENTER, JR., of Philadelphia—There was one point in my paper in regard to prism exercise for the muscles, which I did not have time to read; that is the value of using the prism exercises after an operation that has not produced sufficient results, I mean immediately after the operation. The result of such exercise has in some cases done permanent good and increased the effect of an operation that was not sufficient; this is especially applicable when the hyperphoria is of low degree and yet a disturbing element. A point that we should not forget is that the entire strength of the vertical muscles is represented by 2 to 4 degrees and a defect of 0.5 degrees even is a serious burden for these muscles.

Dr. A. E. PRINCE of Springfield—I want to call attention to a point that has occurred to me in regard to discovering a small amount of hyperphoria that does not render itself apparent upon application of the rod test. It is by sursumduction: in this way, do not commence with the weak prisms and run up, but take a prism that will give you diplopia and then go to weaker ones. That gives the balance and you will find indications that will be quite useful. I will make it clear by a case

which had been examined by different men and showed no hyperphoria. I found that if I used a prism that gave diplopia, one of 4 degrees, and then used a 3, 2.5 and 2 degrees prism, and then worked the other eye in the same way, that they come together, one at 2 degrees and one 2.5 degrees, so there was 0.5 degree difference. By putting that correction in the glasses the little patient was entirely relieved of all trouble.

AMBLYOPIA EX ANOPSIA, WITH CASE.

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY A. C. SIMONTON, M.D.

SAN JOSE, CAL.

The only apology that need be offered for presuming to discuss the question of amblyopia ex anopsia before this learned section of the AMERICAN MEDICAL ASSOCIATION is to state the existing fact that in this year 1897 there are eminent ophthalmologists who deny the possibility of the occurrence of the said condition. It would seem that this question should have been definitely settled long since, but it was discussed extensively, *pro* and *con*, at the meeting of this ASSOCIATION in 1893, and at this meeting we are to have some more *pros* and *cons*, no doubt.

How any ophthalmologist who observes closely, thinks clearly and weighs well the terms he is using, will venture to assert that there is no such condition as amblyopia ex anopsia I shall not attempt to explain. While it is a fact that it has not fallen to the good fortune of many oculists to observe the restoration to perfect vision of an eye almost totally blind from disuse, yet many ophthalmologists have observed many cases in which there has been partial restoration of vision after a strabismic eye has been rendered parallel with its fellow. But the restoration not being complete they assert, by the careless line of reasoning and expression before mentioned, that inasmuch as there yet remains amblyopia, the strabismus was caused by original amblyopia and not amblyopia by the strabismus. But when it is acknowledged, as is the case by all authorities, that in a strabismic eye which is highly amblyopic a large percentage of vision may be acquired when the eye is rendered parallel with its fellow and the function of fixation established, is it not equivalent to acknowledging, at least, that the vision thus gained had been in abeyance by reason of lack of use? If so, does not that constitute amblyopia ex anopsia? If this eye, which gains much vision, had always been parallel with its fellow, does any one suppose for a moment that its visual power would ever have fallen below the full amount now gained by virtue of use in later life? Whether such eye had an original defect which would have rendered it more or less permanently amblyopic or not, it is clear that to the extent vision is restored by use, vision had been lost by virtue of non-use. If one-fourth, one-half or three-fourths of the visual power may be lost or never acquired in a strabismic eye by non-use, is it not logical to conclude that in many cases the total loss in visual power is attributable to this cause? If not logical then why not?

No doubt quite a percentage of eyes become strabismic because of opacities of the cornea, lens or other media, or defective retina, and we find the same class of individuals who deny the existence of amblyopia ex anopsia contend that all strabismic eyes become so by virtue of defect of vision in the converging or diverging eye, and not on account of any conditions relating to accommodation and convergence as

maintained by Donders. But all agree that there is frequently partial restoration of vision; therefore, there must have been partial amblyopia ex anopsia. And as said before, if part of an amblyopia may be due to want of use the total amblyopia may be thus caused.

The members of our profession who admit fully the existence of amblyopia ex anopsia are also those who agree with Donders that convergent strabismus in a very large majority of cases is due to hypermetropia. The question is raised by those who deny the existence of amblyopia ex anopsia that if convergent strabismus is caused by hypermetropia why do we not have a thousand cases for every one that now exists, since the number of hypermetropes is very great compared with the cases of strabismus? But why are there comparatively so few cases of strabismus when there are so many cases of hypermetropia, has been asked many times and long ago. All students of physiologic optics are familiar with the relations that exist in emmetropia between accommodation and convergence, that these relations are co-ordinate and reciprocal. Now while it is true that under exactly normal conditions there is precisely a given amount of convergence corresponding with a given amount of accommodation, yet these conditions are frequently in abeyance for one reason or another; therefore there is another fortunate possibility on the part of human eyes provided for, and that is the power of *dissociating* the two functions of convergence and accommodation. All know how this must be done in adult life in the use of optic instruments, and in presbyopia when spectacles are used. But in adult life, after the individual has long enjoyed perfect binocular vision, there has supervened a greater adaptability to varied visual conditions than possibly existed at a time when binocular vision at the near point was being established in infancy.

In a certain percentage of children this power of disassociating the two functions of convergence and accommodation is nil; in other words, they have no relative range of accommodation and convergence. In an infant who can not disassociate these functions and in whom hypermetropia exists there must inevitably follow convergent strabismus, since accommodation and convergence must be equal. This to my mind is the exact reason why a certain per cent. of hypermetropes become strabismic when accurate binocular vision at close range is being established, and this without the existence of any defect of vision on the part of the converging eye. And again, this theory will explain why it is not necessarily in high degrees of hypermetropia, rather than how, that strabismus occurs.

It is not nearly so difficult to ignore, mentally, an indistinct image in an eye out of parallel with its fellow, as many are given to suppose. Quite occasionally in our tests of muscle equilibrium we find that our patient, although possessed of good binocular vision, can with difficulty recognize the second image produced by the use of prisms.

But when the focal point in a strabismic eye falls upon the disk, as it often does in convergent strabismus, there will be no nervous impression to ignore. It is in these cases of convergent strabismus where the focal point falls on the blind spot that we have early amblyopia, and if conditions are allowed to continue almost total loss of vision in a few years. It is different in divergent strabismus. In this case the

focal point falls on sensitive retinae outside the macula. It has been my observation that in outward deviation the amblyopia is not nearly so great, as a rule, as in the convergent form. In many cases a large amount of vision remains in a divergent eye and yet the person is not troubled with double vision in the least. Close the habitually fixed eye and fair vision will be manifest in the diverging eye. Some of these patients, no doubt, use their eyes alternately, as is the case with many of the lower animals whose eyes are so placed as to preclude binocular fixation. It seems that these animals have the power of acute vision with either eye while ignoring the image in the fellow eye for the time. At all events it remains a fact that in divergent strabismus, in many cases, quite a percentage of vision remains in the divergent eye with no recognized diplopia. But on account of the fact that the focal point does fall upon sensitive retina, although said impression is not recognized in the sensorium, it results in preserving to a greater extent the function of the nervous apparatus of the eye than would be the case did the focal point fall upon the blind spot.

So few have been the cases reported of complete restoration of vision of an eye that has been strabismic and amblyopic that the profession is almost incredulous in regard to such reports. Learned ophthalmologists were surprised by the report of a case by Dr. Johnson at the Milwaukee meeting of this Association in 1893, in which case there was complete restoration of vision in an eye that had been strabismic and amblyopic from early infancy, to the extent that vision was almost *nil*. Some of these able confrères remarked that it was the first and only case that had come to their notice seeming to establish the doctrine of amblyopia ex anopsia, forgetting, as I have stated before, that partial restoration of vision of an amblyopic eye is as much evidence of amblyopia ex anopsia as full restoration.

In concluding this paper I will report a case, in my own practice, in which a highly strabismic and amblyopic eye was restored to perfect vision by correcting hypermetropia alone.

Case.—March 31, 1892, Pauline C., aged 8 years, was brought to my office for consultation about strabismus of the left eye, which had existed from the age of three years. The convergence was in high degree. Owing to the fact that fixation of the left eye had practically always been in abeyance, it was somewhat difficult to assume this function with the right eye covered. Our first test of vision elicited the information that the patient could recognize her father at about five feet, and recognized a pencil held in the hand at four feet, but could not tell how many fingers were held before her at this distance. I attributed this low state of vision on this occasion to inability to fix the left eye. Vision of right eye was 16_{60} , and with — spherical I D. she read in part 16_{30} . Plus glasses obscured vision more. Owing to meager vision manifested by the left eye at short range I did not test acuity of vision at distant letters. I put the eyes under the influence of duboisia for further and better examination. R. V. $\times 200$. With + S. 2 D. read 16_{20} . Here was positive evidence that ciliary spasm had existed in this case making an apparent myopia in a case of hypermetropia. Under duboisia and with + S. 2 D. the left eye now read indistinctly, 16_{60} . This was the best vision that could be obtained with lenses. Skiascopy confirmed the existence of 2 dioptres of hypermetropia.

I placed + 2.50 S. before these eyes and sent the child home, the eyes being fully under the influence of duboisia. I hoped on account of the vision remaining in the left eye to be able to overcome the strabismus and acquired amblyopia by glasses alone. The sequel proves that my hope was well founded. It will be observed that I gave over-correction. The

patient called at my office April 4, 1892, when I discovered the eyes were about parallel. On April 9 strabismus had disappeared. At this time, with + S. 2 D., read $\frac{1}{4}$ with left, showing quite an improvement. I directed that the right eye be covered for two hours each day for distant vision. July 13, three and a half months after adjusting glasses, distant vision of left was $\frac{1}{4}$, and medium print at fourteen inches. I have seen this patient often since the last date and vision is perfect. I have continued, from the first, the use of 2.50 D. lenses, both for distance and near. They blurr distant vision slightly, but are no detriment at the near point. My reason for continuing the strong glasses is that the tendency to squint has never disappeared and the instant the glasses are raised from the eyes the left one again converges.

While this was not a case of the most extreme amblyopia, yet it was amblyopia in quite high degree, and it demonstrates most clearly that the strabismus was not due to original amblyopia, for there is none finally left. It demonstrates, also, as clearly as though the case were an extreme one, that the entire amblyopia was due to the strabismus, and if the strabismus had continued a few years longer vision would have been almost totally lost in the left eye. There is nothing clearer to my mind than that this conclusion is correct, and there is such a condition as amblyopia ex anopsia.

AMBLYOPIA FROM SUPPRESSION, CONGENITAL IMPERFECTION OR DISUSE: WHICH OR ALL?

Presented to the Section on Ophthalmology, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY LEARTUS CONNOR, A.M., M.D.
DETROIT, MICH.

Since different writers use the term "amblyopia ex anopsia" to express radically diverse ideas, it is needful to define its meaning in this discussion. Negatively it is not applied to a dulness of vision induced either by an organic lesion, which can be objectively seen with the ophthalmoscope or otherwise; nor by exclusion of light from the retina, in part or whole, during long periods; nor by defective refraction or disturbed muscular equilibrium of either ciliary, rectus or oblique muscles. Positively it is applied to that dulness of vision which attends the inability of the brain to recognize impressions sent it from the retina.

As to the nature and causes of the dulled vision, we have three widely differing views. The first contends that the brain actively inhibits the visual center from receiving impressions, until it loses its receptive power in whole or part; the second says that the brain or visual center was not properly constructed; while the third argues that the phenomena result from simple disuse, like the disability induced in other organs by a cessation of much or all of their functional activity during a considerable period. The relative importance of these views is of a practical nature. If we adopt congenital imperfection, it matters little whether cases of squint with amblyopia are operated upon early or late; whether the refractive defects be corrected at once or at convenience; the visual results will be the same. If suppression be accepted, then it were criminal to delay in the rectification of those causes which

are believed to induce the loss of sight, lest the inhibitory power of the brain continue to the production of absolute blindness. If the amblyopia be regarded as due to simple disuse, then surely every consideration prompts to an immediate restoration of the fullest functional activity.

Ophthalmologic literature affords abundant authority in support of either of these views, and of the practice based thereupon. In this state of the question, discussion by experts is of more than passing moment, and to secure such discussion from this Section is the object of this paper.

The suppression view of amblyopia claims that the brain, being disturbed by conflicting images sent it from separate eyes, inhibits the visual center from recognizing the least perfect one. Frequent repetition of this inhibition, at last, so changes the cell action of the visual centers that they become unable to recognize the imperfect image. These imperfect images are due to a variety of causes, as refracting errors, muscular derangements individually or combined in all sorts of ways. On the suppression view there could be no amblyopia except for imperfect images sent to the visual center and so none without lack of muscular equilibrium, or refractive errors alone or variously combined.

The congenital imperfection view of amblyopia affirms that the visual centers were never normally developed or, if developed, were damaged anterior to birth; it is uncertain whether the defect be in the brain outside or within the visual centers, in the retina or optic nerve fibers. The central scotomas of many cases suggest a pathologic anatomy like that of the toxic amblyopias; they are sometimes for form alone and sometimes for both color and form.

A presumption against the suppression view arises from the fact that in no other instance is it claimed that the brain, by inhibition, actually destroys the functional activity of any organ beyond possibility of restoration. We have many illustrations of imperfectly formed organs, as clubfoot, harelip, colobomas of the iris, retina or choroid, but we know of no organ born with normal development, rendered imperfect by the capricious dislike of the cerebrum.

To determine what light, if any, clinical evidence would throw upon this subject, I studied 7,500 recorded cases of imperfect vision, all from private practice. The standard of amblyopia adopted was an inability to see 20/40 or more after correcting all defective refraction, under full mydriasis, removing all muscular disabilities and securing a normal condition of the general health. Of these above 4,000 were anisometropic, but only sixty were amblyopic; showing that amblyopia was a very infrequent attendant of anisometropia, and so unlikely to be caused by it. Anisometropia was found a frequent condition in all cases of convergent squint, but of the fifty-four amblyopic squint cases, only twenty-two were anisometropic. As there was more than three times as many cases of non-amblyopic as of amblyopic squint, it is plain that anisometropia was an unimportant factor in causing amblyopia in the squint cases. Thus my own observations give no reason to believe that anisometropia is a factor in causing amblyopia. According to the suppression view squint is regarded as an important factor in producing amblyopia, while according to the imperfection view, the amblyopia aids in causing squint.

My records do not exhibit a single instance of ambly-

opia among cases of vertical squint: though on the suppression view we should have expected a proportion similar to their frequency in other varieties of squint, because there must have been at the beginning an equal degree of confusion among the images sent the brain. Of 219 cases of convergent squint only fifty-four were amblyopic, a small proportion if squint was an active cause of amblyopia. Of fifty-four amblyopes that squinted only twenty-two were anisometropic; so that neither the squint or the squint combined with anisometropia were important factors in producing these cases of amblyopia. Of 127 cases of amblyopia, only fifty-four ever squinted. It thus appears that the majority of cases of convergent squint are not amblyopic, and the majority of amblyopes do not squint; evidence weighing strongly against squint as a cause of amblyopia.

Donders showed that hyperopia accompanied most cases of convergent squint, but farther studies prove the problem far less simple than he thought. Thus, since the normal condition of all eyes at birth is hyperopic, why does not squint occur more frequently? The suppression view says that hyperopia causes confused images, which induce the brain to inhibit the visual centers and thus cause amblyopia. In truth, only few hyperopes squint, and very few are amblyopic. The facts militate against the suppression view here also. Incidentally the facts seem to show that lack of muscular equilibrium rather than either hyperopia or imperfection of the visual centers, is the essential factor in causing squint. In common with others, notably Dr. Valk, I have found that the normal power of the internal rectus to that of the external is as four to one. If this be changed, we have convergent or divergent squint according to the refractive defect; if it remain unchanged there is no squint. On the assumption that squint caused amblyopia, we should expect that the cure of squint by operation, or the correction of existing refractive defects or exercise, or a combination of all, would improve vision, but I am unable to find a single case with central scotoma in which the vision was materially improved. Other cases were improved in the ability to use the eyes for longer periods, but their actual visual acuity was unaltered. On the suppression view we ought to find cases in which the squint or anisometropia remaining uncorrected, the sight became progressively worse to such a degree that even the patient would note the loss; but I have failed to find such cases.

Then, if all eyes were born with normal vision, some observer ought to have noted good vision in an eye which afterward became amblyopic, and thus demonstrated the fact of suppression. I am aware of the difficulty attending such studies, but it has happened to me to occasionally meet with a child so tractable as to admit of a satisfactory determination of its vision and refraction by objective and subjective methods, and I have failed to observe any loss of visual power without a cause recognizable with the ophthalmoscope. Nor have I found any reports of such observations. Hence, we have no direct proof of the suppression of good vision as a cause of amblyopia.

We do find cases of children born with monocular amblyopia. Twenty such I found in my own records, and Schweigger reported ninety-eight having varied defects of refraction. They could not have been caused either by squint, anisometropia or disuse, and so must be from congenital defect.

It is claimed that cases of scotoma like those found

in squinting eyes are unknown; but my records show twenty cases who never squinted, and yet exhibited a central scotoma of more or less density. Possibly these might be found more frequently, were they carefully looked for. It is reasonable to ascribe these similar scotomas in both squinting and non-squinting eyes to the same cause. That of suppression being untenable, congenital defect must be accepted. As diplopia from ocular paralysis, even in the very young, is a source of distress, we should expect to find some indication of such distress antedate the development of amblyopia, but I have no indication of such distress, though I have often looked for it. Monocular amblyopia, with central scotoma, without squint or anisometropia, would seem to form a combination impossible to account for on any other view than congenital defect. I found four such cases, aged 6, 13, 19 and 45 years. As far as the most searching investigation could determine, there had never been any squint, the scotoma had existed at birth, and there was no anisometropia.

Case 1.—Ava P. Bancroft of Michigan, aged 6 years, brought to me Sept. 4, 1891, by her physician, Dr. Harvey, on account of defective sight. Vision of right eye, 20_{200} ; left eye 4_{200} . A total hyperopia of plus D. 2.50 S. was found in each eye, by the ophthalmoscope and retinoscope, and subjectively confirmed by test objects. The examination was made before mydriasis, under mydriasis and after it had passed off. The correction of the total hyperopia gave the right eye vision 20_{50} ; the left 20_{100} . In the left eye the vision was best at the left of the median line both for color and form. Dr. Harvey had noticed the defective vision three years previous, and no change had been observed by either the doctor or the parents. A re-study of the case two years later showed the vision and scotoma unchanged.

Case 2.—Miss M. A., Toledo, Ohio, aged 19 years, was seen March 13, 1887, on account of intense headaches. Vision of right eye, 20_{40} ; left eye fingers at six inches and only at the borders of the visual field with any distinctness. Under mydriasis vision of the right eye = 20_{20} with plus D. 2.25 S. \odot + D. 0.50 C. ax. 60. Determined objectively by ophthalmoscope and retinoscope the refraction of the left eye was the same as the right, but its vision was not materially increased by its correction. Two years later, patient reported entire relief from headaches while wearing full correction of the defective refraction, but there was no change in vision. Her father, a careful physician, said that he had observed the defective vision before any attempts of the child to read letters, but had never noticed any squint.

Case 3.—Miss A. H., Windsor, Ontario, aged 13 years, on June 14, 1881, consulted me for dimness of vision in her right eye. Vision of right eye, 2_{200} ; left eye 20_{50} . Under mydriasis she was found to have a hypermetropia of two dioptrics in each eye. The correction of this increased the vision of the right eye to 6_{200} ; left eye 20_{20} , Jaeger No. 1. The right eye had a large scotoma for both form and color. Five years later the condition was practically the same. No history of squint could be obtained from either patient, friends or family physician.

Case 4.—Miss F. H. H., aged 45 years, consulted me June 10, 1890, for a dimness of vision. Her uncle, an accomplished physician, in whose family she had been born and reared, said that before she was two years old the defect in her left eye was noticeable, and had remained unchanged, but he had never observed any squint.

V. O. D. = 20_{40} , 20_{30} w. — D. 1.00 C. ax. 90° \odot + D. 0.75 S. : J. 1, w. + D. 2.25 S.

O. S. = 20_{200} w. — D. 1.00 C. ax. 90° \odot + D. 0.75 S. J. 13, w. + D. 2.25 S.

In this case the amblyopia was observed long before any attempts to read, there was an absence of anisometropia and any tendency to squint. There was a central scotoma of the left eye like that found in cases of squint.

In each of these cases, as there was complete absence of all the causes of suppression of defective images, the amblyopia must have been from congenital defect.

The data thus far presented show that the existence of amblyopia from suppression is at least doubtful, while that from congenital defect is certain.

There is another class of cases, often confounded with true amblyopia, and so causing much confusion in both thinking and practice. Hence it is necessary to consider it in this connection. Their vision is more or less diminished, there is no scotoma, and they improve under appropriate management. This impaired vision is from disuse more or less complete from a variety of causes, as refractive defects, lack of muscular balance, from constitutional disease, overwork, etc. Any disuse of the eye operates unfavorably upon visual acuity by impairing the power of fixation, by giving imperfect control of accommodation and by rendering the retina easily fatigued. In these cases sight is often improved and occasionally entirely restored by removing the occasion of the disease. Illustrative of this is the following case; that the subject was approaching middle life shows that improvement of these cases is not confined to childhood.

Mr. G. W., a lawyer, aged 36 years, on Aug. 22, 1885, consulted me for poor sight in his left eye. The ophthalmoscope revealed no organic change in either eye. Vision of right eye was $\frac{20}{40}$; left $\frac{20}{100}$. J. N. 4 with right eye, No. 10 with left eye. Under mydriatic, the right eye gave vision $\frac{20}{30}$ with + D. 1.25 C. ax. 180° \ominus D. 1.00 S.; the left eye $\frac{20}{40}$ with plus D. 1.50 C. ax. 180° \ominus + D. 3.50 S. On recovering from the mydriatic, with correcting glasses he could read J. No. 1 with right eye and J. No. 4 with left. He was directed to wear the glasses constantly, soak his eyes in hot water ten minutes after concluding work daily. Five months later vision of right eye was $\frac{20}{20}$; left $\frac{20}{30}$. Since, at intervals, his glasses have been changed to meet advancing presbyopia, until Dec. 26, 1896, with glasses, vision of each eye was $\frac{20}{20}$ and J. No. 1.

Not all cases give as favorable results, owing doubtless to lack of faithfulness on the part of the patient, or often from complicating actual defect in the visual apparatus less than occurs in amblyopia, though of the same nature.

In children these cases are often benefited by compulsory use of the bad eye, and of a magnifying glass for near objects, by turning them out of doors as much as atmospheric conditions will permit, and otherwise adjusting their lives so as to develop the greatest physical vigor.

Cases are reported of the speedy cure of the amblyopia of a squinting eye after the destruction of its fellow. Thus, Dr. Walter B. Johnson (*Amer. Oph. Jour.*, January, 1894) reports two cases. In both the good eye was destroyed by accident. In one the squinting eye sufficed to count fingers, but normal vision was established ten days after the accident. The second case was a man 30 years of age, with a history of convergent squint from childhood. At 16 he discovered that he was unable to read as well with the right eye as with the left, and no glass which he could select at the optician's greatly improved his sight. At 17 he was operated on at the New York Eye and Ear Infirmary. On Aug. 28, 1893, while working at his trade, his left eye was so injured by a piece of iron as to reduce vision to the counting of fingers at six inches. The vision of his right eye as tested by Dr. Johnson just after the accident was $\frac{20}{70}$, not improved by glasses. Four days later the vision of the right eye was $\frac{20}{30}$, with or without a plus 1.24 S. Three months later he could merely count fingers with the injured eye at six inches; with the right eye vision was $\frac{20}{30}$, or with plus 1.24 $\frac{20}{10}$.

I have one case of the same nature in which the result was less satisfactory.

E. B., aged 28 years, a laborer in the Penin. Car Works, was brought to me for an injury to his right

eye on Nov. 26, 1890. He and his friends said that the left eye always converged, and that he never could see anything with it. The accident had torn the eyelids, smashed through the eyeball, tearing the ciliary body, the lens and sclerotic in such a manner as to practically destroy all sight. Because of the blind left eye every effort was made to save some sight in the right eye, but to no purpose. An examination of the squinting eye, at the time of the accident and many times thereafter, failed to detect any disease of either optic nerve or any of the media, choroid or retina. There was mere perception of light at the periphery of the visual field. This perception did not increase to any appreciable degree, nor has it done so when last seen, three years after the accident.

The explanation of these cases is that one is from congenital defect and the other from disuse. The amblyopia from disuse develops its latent power when the necessity for the same presents; the other having no latent power because of congenital defect, and so remains blind, even after destruction of its fellow eye. In my case, there was certainly a central scotoma, and the history of Dr. Johnson's cases would seem to make evident the fact of a normal field of vision, as no mention is made of a scotoma.

Conclusions.—1. There are undoubted cases of amblyopia from congenital imperfection; characterized by central scotoma, and being unaffected by any treatment; they are found in eyes that squint and eyes that do not squint, in the hyperopic, astigmatic, the anisometropic and in eyes free from one or more of these defects.

2. There is no positive evidence of the existence of amblyopia from suppression, viz., a loss of sight from the inhibitory action of the brain upon the visual center.

3. There is a class of cases often confounded with amblyopia, characterized by lack of persistent vision, rather than absolute loss; by the absence of scotoma; improved often by proper management, is never congenital; found in all varieties of refraction and all sorts of muscular disturbance; having the same nature as diminished functional power of any sound organ from non-use or diminished use.

4. There is a class of cases in which a congenital amblyopia is still farther crippled by disuse; in these proper management often produces satisfactory results in removing the latter factor.

5. It therefore remains good practice to study every case of amblyopia with or without squint at the earliest possible moment, correct its refractive defects and restore its muscular equilibrium, because, while we can not repair the congenital imperfection, we may remove the disability from disuse and thus secure some improvement of vision.

103 Cass Street.

DISCUSSION.

Dr. H. M. STARKEY of Chicago in opening the discussion said: The author of the paper has covered the ground so completely from a theoretic standpoint that little remains to be said in that direction. The definition he proposes is new to me and gives quite a different conception of this term from that previously held by me and from that usually held, if one may judge from that given in most text books. I did not suppose that amblyopia ex anopsia is usually applied solely to cases in which there is inability of the brain to perceive images impressed upon the retina. We have found, as Dr. Connor has, that much confusion arises from considering several different conditions under the same name, but if we restrict the term amblyopia ex anopsia to those cases in which the brain refuses to receive images, we are under the necessity of coining another term for the cases that have usually been so called, while we are not at all

certain that we have any cases to which the term may be rightfully applied. As the author has well stated, we have little or no evidence that amblyopia is ever due to suppression, by the brain, of an impression that has been properly conveyed to it. But if the generally accepted meaning is given to this term, namely, that through non-use of the eye the faculty of vision is lessened or lost, we must, unless we ignore facts, admit that such a condition exists. We most of us, I am sure, see cases of defective vision in one or both eyes, in which after careful stimulation of the sight under favorable conditions, the vision improves. There are two classes of these improvable cases. The first class includes young persons having a high degree of ametropia and who, consequently, have never seen clearly. Many such young people, after careful correction of the ametropia, will have vision only one-fourth or one-half normal, but after they have worn the correcting glasses for a few months, vision improves so that they see 50 or 100 per cent. better with the same glass than they did when the glass was first prescribed.

The second class contains persons having strabismus with habitual disuse of one eye. We all recognize that there are many strabismus cases in which there are central scotomata and which are doubtless congenital, in which an improvement of vision is possible; but on the other hand, there are many strabisms in whom a very decided improvement in the vision of the deviating eye can be brought about by systematic and persistent use of that eye. So frequent is this improvement, that it is my custom in treatment of strabismus to first correct any refractive error present and then direct systematic use of the deviating eye, deferring the operation till a later time. And in a considerable proportion of cases, I expect and secure very decided improvement both in the position and in the acuity of vision of the deviating eye. Whether we call the condition present in these cases amblyopia ex anopsia, or by some other term, is beside the question. The condition is present and can be improved. I repeat this statement because I have lately heard a prominent teacher in a neighboring city make the statement to his class, that the amblyopia found in the deviating eye in strabismus is never due to disuse and is never materially improved by operation or by any other means. I will give a brief outline of a few recent private cases illustrating the points I have tried to make. I have the original records of the cases, so that any of the members of the Section who desire to do so may examine them.

Case 1.—Gertrude P., schoolgirl aged 15, referred to me July 17, 1896, by Dr. C. S. Bacon. Vision right eye 20_{20} — not improved by any lens; vision left eye 20_{200} with 4. D. C. axis 170° 20_{30} —. The vision of the left eye has gradually improved until at the last examination, a few days before I came away, she saw with the same lens the 20 line better than she at first saw the 30 line.

Case 2.—Lottie S., schoolgirl, aged 13 years, referred to me Feb. 3, 1897, by Dr. F. C. Schaefer. Vision right eye 20_{200} with — 3.50 D. S. — 7. D. C. axis 10° 20_{50} ; left eye 20_{100} with — 1.00 D. S. — 7 D. C. axis 180° 20_{50} —. With these lenses, February 24, vision was 20_{60} , and 20_{40} , and May 17 it was 20_{40} and 20_{30} except that one letter was missed in each line.

Case 3 is the most marked case of improvement in a deviating eye that has come under my observation, though numerous others could be cited with marked improvement. Gertrude R., schoolgirl, aged 9 years, was referred to me for convergent strabismus, by Dr. John H. Hollister, July 19, 1894. The vision at that time in the deviating eye was 10_{200} , and with careful correction under atropia, 20_{200} . Under proper use of the eye vision steadily improved, being in August, 1894, 20_{70} , in October, 1894, 20_{50} , in December, 1894, 20_{40} , in July, 1895, 20_{30} —, in May, 1896, 20_{30} +, and in October, 1896, 20_{20} , and she now sees with this same eye most of the letters in the 15 line at twenty feet.

Dr. D. W. STEVENSON of Richmond, Ind.—I quite agree with Dr. Starkey that the definitions in the text books do not quite agree with that of Dr. Connor. Amblyopia may exist with three conditions: 1. When there is no central fixation; 2, where there is, and 3, where there is lack of use. A person may have fairly good vision and yet not have central fixation. And here I would urge in examining children with muscle trouble, even if only 2 or 3 years of age, that it is important to treat them as thoroughly and carefully as older people, for if we can only guide that child to central fixation, it may prevent disfigurement in later life. Central fixation can only be learned in childhood. You can not expect a child whose vision has been blurred to learn central fixation in after years, for it can probably only be learned in the first few years of life. We note the difference in operating upon congenital and senile cataracts; in the latter though it may have lasted forty years, if he learned central fixation in youth he will still be able to fix. The im-

portant point we ought to learn is to look after these patients year by year until we operate upon them, and we ought to take every means to force them to learn central fixation.

Dr. C. H. THOMAS of Philadelphia—I remember the case of a child 4 years of age, who was able to be tested by test-types almost as well as an adult. He had strabismus on alternate days. It was on this account that I tested his refraction under mydriasis and found him practically emmetropic, full 20_{20} in each eye. After a year or more the strabismus settled down to a strong convergence of the left eye. This continued a year or so when I discovered that he was losing his vision in the left eye, it had fallen to 20_{50} . I then operated and the relief obtained was considerable from the complete section of one internus, but there was something like 8 degrees remaining uncorrected. I performed a partial tenotomy of the fellow eye and obtained perfect balance. Within a year the vision was restored in the amblyopic eye and remains perfect to this day. He is now a grown man and I have examined the eye within the last few days; his vision is full 20_{20} in either eye. I had him under careful observation in the stage of perfect vision, in the stage of developing amblyopia and in the stage of perfect recovery.

Dr. J. L. THOMPSON of Indianapolis—While you may operate upon a man for cataract, and he will have just as good vision in one eye in which cataract has existed for a long time as in the one of shorter duration, I take it that nature seems to abhor a deviation as she does a vacuum.

Dr. WALTER B. JOHNSON of Paterson, N. J.—I have been interested in this subject for a long time. None of us would want to make the statement that there is no such thing as congenital amblyopia and not many of us would, in the light of occurrences, be willing to say there is no such thing as amblyopia ex anopsia. I think the suggestion that Dr. Connor made in regard to cases in which amblyopia, apparently from suppression, had developed, has been substantiated in many instances. I reported a case two years ago, at the American Ophthalmological Society, of a girl of 12 who came to me first with diplopia and in the course of a short while passed from observation. The diplopia having passed she was comfortable, and in the course of a number of years I saw her again. Her vision at first had been perfect, but in the eye which is now squinting it is only 20_{60} . Now from the other side of the question, coming from lost to improved vision, I have reported two cases, one to the American Ophthalmological and one to the Ophthalmic Section of the Academy of Medicine. In both cases the good eye was lost, one requiring enucleation and the other by traumatic cataract. In each case the vision, in what had been the poor eye, returned to normal within three weeks. I know that in these cases we did not see anything with the ophthalmoscope, and, as Dr. Thompson has said, we can not yet view the cerebral apparatus.

Dr. G. C. SAVAGE of Nashville—Nature in my judgment has two methods of preventing diplopia; one the deviation of the visual axis and the other the suppression of the object mentally. In the lower forms of heterophoria and in orthophoria the method adopted is to cause the visual lines to cross, but in the higher degrees of heterophoria the other method is the one chosen, and it is applicable only in the earlier years of life. Every one of us knows that a squint developed late in life is always attended by double vision. It is too late for the mind to bring about the process of suppression and the patient must get on with double vision unless he covers one eye. The author of the paper has stated that there are cases of amblyopia in which there is no perceptible squint. We have other muscles than the recti.

I want to place myself on record in regard to one point about squint, that is, that when we have a squint that has existed from early life and yet vision as good in one eye as in the other, we are tampering with a case that will confuse us as we go further with it and which is almost impossible of correction.

Dr. G. E. DE SCHWEINITZ of Philadelphia—It was with much interest that I heard Dr. Connor's classification and investigation of the scotomas present in these cases. I have made a similar study. You find cases of squint, with amblyopia, in which the ophthalmoscopic picture, the visual field, etc., are perfectly normal; the vision can be improved with exercise; in others in which there is a distinct scotoma, neither exercise or anything else improves the vision. In a third class in which there is not an entirely normal ophthalmoscopic appearance, inasmuch as there are some changes about the macula, and the visual fields are similar to those produced by retinal tire the visual acuity is capable of a certain amount of improvement.

Dr. LEARTUS CONNOR—You see from the discussion how necessary it was to define what we meant. The amblyopia to which I referred, you will remember, I characterized as being always attended with central scotoma. The cases reported here were not so attended. Now, to confound such cases, that

are due to defects of refraction or lack of muscular balance, is simply confusing conditions, and I think it very important to use the same measure in all our work in these cases. I started out, too, with the idea that the ordinary definition was the correct one, but I found it used very differently by those who believe in the suppression theory. I correct, under mydriasis, and attain all the improvement I can, correct all the muscular equilibrium and then if there is loss of vision I report it as amblyopia. Such cases are absolutely incapable of benefit. They may be attended by the results of disuse as in other organs.

REPORT OF EYE EXAMINATIONS IN THE MINNEAPOLIS PUBLIC SCHOOLS.

TOGETHER WITH REPORTS OF THE EXAMINATIONS OF THE MOTORMEN OF THE TWIN CITY RAPID TRANSIT COMPANY, AND THE LOCOMOTIVE ENGINEERS OF THE MINNEAPOLIS, ST. PAUL AND SAULT SAINT MARIE RAILROAD.

Presented to the Section on Ophthalmology at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY FRANK ALLPORT, M.D.

CHICAGO, ILL. (FORMERLY OF MINNEAPOLIS).

While it is true that a large proportion of school children possess inadequate distant vision, or irksome close vision, or but little vision at all, and are thereby unequally provided with a most important sense, which places them at a decided disadvantage in the world's arena, with its struggling, pushing applicants for place and power, and while it is of the utmost importance that such deficiencies be overcome by the application of modern ophthalmologic therapeutics, yet the search by our profession for an efficient and practical remedy for the general detection and relief of such infirmities, has not been crowned with success.

Undoubtedly ideal results could be obtained in detecting and relieving ocular defects in school children, through their systematic and personal examination by properly qualified oculists appointed for such work by boards of education, as was accomplished in Philadelphia some years ago by Risley, Randall and others. But the "City of Brotherly Love" is happily possessed of a singularly united and harmonious profession, with an inherent *esprit du corps*, rendering possible many professional movements practically unfeasible elsewhere, under circumstances of professional jealousy and strife. The writer feels therefore that the Philadelphia plan, while most desirable, is not generally possible, and that another method, simple, inexpensive and reasonably accurate in character, possible of manipulation by the laity, applicable to all cities, of a non-compulsory nature, giving free liberty as to choice of consultant and rendering impossible personal contact between a board appointee and the school children, except as they come as private or dispensary patients, should be devised and endorsed by ophthalmologists.

With this end in view the writer, Feb. 6, 1895, presented a paper to the Minnesota Academy of Medicine, which was published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, March 2, 1895, embodying a plan for the systematic examination of school children's eyes by school principals. This plan was received favorably by the Academy and a formal request was forwarded to the Minneapolis Board of Education, requesting its adoption, but owing to reasons probably satisfactory to itself, the Board practically tabled the request until the election of the new Board in January, 1897, when it was promptly adopted and the writer appointed as Board oculist.

But in the interim the writer has been given an opportunity of teaching the method at the University Summer School, and before the senior class in the department of pedagogy in the Minnesota State University, with the result of seeing it quite generally and favorably received in the University and many adjacent cities.

Drs. Harlan and Wood of Baltimore have used a similar plan, during the past two years, in the public schools of that city, and reported flattering results at the last meeting of this Section in Atlanta.

The expense in Minneapolis has not equaled \$100, a little printed matter being the only requisite, as no salary is involved. The plan, though necessitating some extra labor, has been easily carried into practice, and the principals and teachers are its warmest advocates, feeling as they do, that it is a beneficent movement and will eventually lighten their labors, as the children are placed in better conditions for work and application.

The preliminary eye tests are to be made annually as near the commencement of the fall term as possible, in order to give ample opportunity for the observation of results. The examination should not be conducted in the presence of other scholars, as familiarity with the letters leads to incorrect responses. Children already wearing glasses should be tested with such glasses on the face, as this tends to mitigate any possible opposition from parents and attendant oculists, on the ground of meddlesome interference. It has been found useless, laborious and impracticable to examine first grade children, consequently they may be excluded from the tests.

One of the chief obstacles to success in the Minneapolis tests has been the consulting of opticians instead of oculists, through the fulsome circulars and advertisements of the former which were thrown broadcast as soon as the tests began; and the prevalent impression that this has been merely a test for glasses, and not for the development of ocular diseases in general. This fact leads me to urge principals and teachers to explain and emphasize these matters preliminary to the tests, and from time to time during the year.

The plan is briefly as follows: A superintending oculist shall be appointed by the Board of Education, whose duties shall be to superintend the details of the plan. He shall each year, at the beginning of the fall term, deliver a lecture to the principals upon practical ocular anatomy, physiology, refraction and its errors, the general use of the eye, etc., and shall demonstrate the plan upon from twenty-five to fifty pupils furnished for the occasion. He shall afterward be accessible to the principals for advice and counsel, and shall finally receive the principals' reports and systematically submit them to the Board, together with deductions, recommendations, etc. It will be observed that in an office of this kind there will be but little opportunity for adverse manifestations of professional jealousy, or accusations of unjust pressure upon children from business motives.

It should be first ascertained if the child habitually suffers from red or inflamed eyes or lids, after which the visual tests should be conducted. Snellen's test card should be used for the purpose of uniformity, and the vision of each eye recorded in the proper line of the statistic blank, as 20, 30, 40, 200, 0, etc., instead of 20-20, 20-30, 20-40, 20-200, 20-0, etc., being more intelligible to the laity, bearing in mind that only

defectives need tabulation. The child should be given credit for the smallest line of which he sees a *majority* of the letters, as it has been found inexpedient to be too strict in this particular. It should then be ascertained if the child *habitually* suffers from asthenopia after study, being careful that a correct and thoughtful answer has been secured. This question develops the existence of troublesome hypermetropia, astigmatism, muscular anomalies, etc., while the former question indicates the presence of myopia, astigmatism, cataracts, choroiditis, most cases of strabismus, etc.

If inflamed eyes are not habitual, the vision is normal in *both* eyes and actual asthenopia is not present, the child is not further molested until the next fall examination. But if inflamed eyes are habitual, or the vision is defective in either eye, or asthenopia develops, a card of warning should be sent to the parents urging that an oculist be consulted at his office or dispensary. The principals and teachers should bear these cards in mind and from time to time urge the children and their parents to heed them, though their influence should not be exerted in favor of any particular oculist.

These cards urge the parents to consult an "eye doctor," which is rather a broad expression, but rendered necessary by the fact that many intelligent people do not distinguish between an oculist and an optician, and the cards will go into many homes where dense ignorance prevails. Upon the backs of the cards should be printed the names, addresses and office hours of the different dispensaries.

The fact should in due course of time be chronicled as to whether a pupil has consulted an oculist or not, and the effect that such a consultation has upon his school life, character, physical condition, etc., and when the report is thus completed it should be handed to the Board oculist for presentation to the Board of Education.

This last spring, 25,696 children were thus examined in Minneapolis, of which 8,166 or 32 per cent. were deemed ocularly defective. Amongst these 6,451 eyes were found possessing a vision of 20-30; 2,256 eyes had a vision of 20-40; 1,214 a vision of 20-50; 1,130 a vision of 20-70; 745 a vision of 20-100; 447 a vision of 20-200 and 43 a vision of 20-0. Four thousand four hundred and seventy-two children complained of distinct asthenopia after study. The individual percentages of defectives in the different schools have ranged all the way from 11 to 67 per cent., the latter occurring in a conspicuously poorly lighted and insanitary building.

One of the disadvantages of this plan is the impossibility of obtaining the most accurate and valuable statistics, such as would be possible if all scholars were scientifically examined by a united force of oculists. But enough is already positively known through the information of principals, duly chronicled in the statistic blanks received May 1, to fully warrant the statement that already over 1,000 pupils have been distinctly benefited through the tests, and the matter is only in its infancy as many children will subsequently seek advice when prejudice, ignorance and carelessness have been overcome, or the days of the long vacation are at hand, with more leisure to devote to ocular consultations.

Copies of the statistic blanks and warning cards are here submitted:

MINNEAPOLIS PUBLIC SCHOOLS.

MINNEAPOLIS, MINN. 189 . .

Dear Sir: Your child's eyes have been examined by me this day. I believe it advisable to consult an EYE DOCTOR of recognized standing, and if you feel unable to consult one at his office, a Dispensary will do the work free of charge. Respectfully,
[OVER.] Principal School.

MINNEAPOLIS PUBLIC SCHOOLS.

EYE EXAMINATIONS.

. School. Date 189 . .
Principal Examiner
Entire number of pupils examined
Number advised to consult an Oculist

INSTRUCTIONS FOR EYE EXAMINATIONS.

The examination should be made privately and singly, in a room apart from the general school session.

Ascertain if the pupil habitually suffers from inflamed lids or eyes.

Children already wearing glasses, should be tested with such glasses properly adjusted on the face.

Place a card of Snellen's Test Types on the wall in good light; do not allow the face of the card to be covered by glass.

The line marked XX (20) should be seen at twenty feet, therefore place the pupil twenty feet from the card.

Each eye should be examined separately.

Hold a card over one eye while the other is being examined. Do not press upon the covered eye, as the pressure might induce an incorrect examination.

Have the pupil begin at the top of the test card, and read aloud down as far as he can, first with one eye and then with the other.

If the pupil does not habitually suffer from inflamed lids or eyes, and can read a majority of the XX (20) test type with each eye and does not, upon inquiry, complain of *habitually* tired and painful eyes or headache after study, his eyes may be considered satisfactory, but if he habitually suffers from inflamed lids or eyes, or can not read a majority of the XX (20) test type with both eyes or *habitually* complains of tired and painful eyes or headache after study, a card of information should be sent to the parent or guardian.

Please examine your entire school by this method, but only such pupils as are thought necessary to send to an Oculist need tabulation in this blank.

May 1 of each year please complete this report and send it to Dr. C. M. Jordan, Supt. of Schools, and a duplicate to the Board Oculist, Dr. Frank Allport, 602 Nicollet Avenue, Minneapolis, Minn.

This will afford you an opportunity to examine your pupils, to note if they follow your suggestions, with regard to consulting an Oculist, and if so to observe the effect upon the pupil's conduct, health, application to study, etc., which you will please carefully, but briefly, note in the proper place in this sheet.

First grade children need not be examined.

No.	Name	Sex	Age
Column 1.	Does the pupil habitually suffer from Inflamed Lids or Eyes?		

Column 2.—State number of last line seen by pupil with Right Eye.

Column 3.—State number of last line seen by pupil with Left Eye.

Column 4.—Do the Eyes and Head habitually grow weary and painful after study?

Column 5.—Did pupil consult an Oculist and follow his advice?

Column 6.—Briefly describe the results of treatment.

I beg leave at this time to also report some interesting examinations made the past spring. The writer is not aware as to whether men who run electric or cable cars through our cities are examined as to their ocular and aural condition or not, but at his suggestion the Twin City Rapid Transit Company of Minneapolis and St. Paul, operating electric cars in those cities, requested him to examine the eyes and ears of their motormen. The writer feels there can be no question as to the extreme necessity for such examinations in men driving cars through our crowded thoroughfares, and believes that such examinations should be made obligatory with street car companies, in order to protect the life and limbs of citizens. The writer believes that many accidents could thereby be avoided, and that it would be an excellent investment for all street car companies to know positively that their drivers possess good eye-sight and hearing, and to have on file certificates therefor from reputable examiners, produceable in possible litigation.

The standard adopted by the writer in these examinations was, that at least one eye should possess a vision of 20-30; that a watch should be heard by at

least one ear, at a distance of one foot, and that an ordinarily low voice should be heard by at least one ear; and that color blindness should not exist. The writer is confident that these exactions were sufficiently lax, possibly too much so, but the company requested that as much leniency as possible should be shown to old employes, but that *new* applicants for the position of motormen should be subjected to the closest scrutiny.

At the request of the writer the company also agreed to allow old motormen to wear glasses while on duty, in case they were found necessary, but will not extend such indulgence to new applicants.

The writer examined 218 motormen, and found but one color blind individual in that number. Several men had a weak chromatic sense, but were not distinctly color blind. All of the men possessed sufficiently accurate hearing to enable them to carry on their work. Ten men were found with vision below the standard. I briefly submit their records:

No. 1. J. H. V. R. E. = 20/40, with — 0.75 cyl. ax. 90° V. = 20/20.

V. L. E. = 20/60, with — 1.25 cyl. ax. 90° V. = 20/20.

No. 2. W. H. P. V. R. E. = 20/40, with + 0.50 cyl. ax. 90° C — 1.00 cyl. ax. 180° V. = 20/20.

V. L. E. = 20/60, with + 0.50 cyl. ax. 90° C — 1.25 cyl. ax. 180° V. = 20/20.

No. 3. J. S. V. R. E. = 20/60, with + 0.50 sph. C + 0.75 cyl. ax. 180° V. = 20/20.

V. L. E. = 20/60, with + 0.75 sph. V = 20/20.

No. 4. C. H. H. V. R. E. = 20/100, with — 3.00 sph. C — 1.75 cyl. ax. 170° V. = 20/20.

V. L. E. = 20/100, with — 3.00 sph. C — 2.00 cyl. ax. 10° V. = 20/20.

No. 5. M. K. V. R. E. = 20/100, with — 1.25 cyl. ax. 180° V. = 20/30.

V. L. E. = 20/60, with — 0.25 sph. C — 0.75 cyl. ax. 180° V. = 20/30.

No. 6. M. F. V. R. E. = 20/60, with — 1.25 cyl. ax. 90° V. = 20/30.

V. L. E. = 20/60, with + 2.00 cyl. ax. 90° V. = 20/20.

No. 7. C. A. V. R. E. = 20/70, with — 4.00 cyl. ax. 180° V. = 20/30.

V. L. E. = 20/70, with — 4.00 cyl. ax. 180° V. = 20/30.

It will be observed that all of these seven men were enabled, by the aid of properly adjusted glasses, to obtain suitable vision for their occupation. They were therefore allowed to resume their work, with the distinct understanding that they should obtain the glasses, which should be inspected by the writer, and should always wear them when on duty.

Three cases possessed vision so poor as to render them unsafe for the company to employ, and a menace to the public. Their records are as follows:

No. 1. J. L. V. R. E. = 20/50. Unimproved by glasses. Opaque cornea.

V. L. E. = 20/200. Conical cornea.

No. 2. J. T. V. R. E. = 20/50. Unimproved by glasses.

V. L. E. = 20/50. Unimproved by glasses.

No. 3. D. J. V. R. E. = 20/60.

V. L. E. = 20/200. Vision can be slightly improved in each eye by glasses, but not sufficiently to render him a safe employe.

These last three cases, then, were in the interest of the company and of the public, unconditionally condemned and removed from their positions. The com-

pany, however, indulgently gave them other employment, so that no hard feelings were engendered.

It will therefore be seen that, out of 218 men, seven were required to wear glasses, three removed on account of imperfect and uncorrectable vision, and one because he was color blind.

In conclusion the writer begs leave to report the examination of ninety locomotive engineers of the Minneapolis, St. Paul and Sault Sainte Marie Railroad. About one hundred still remain to be examined, but have not presented themselves up to the present writing.

When the writer presented the subject to the manager, he was met with the opinion that the men had already been examined by one of the railroad employes, and as such matters were very simply performed he regarded it as sufficient. But upon the writer's urging the value of a medical man's certificate, in case of accident, to say nothing of a sense of added security on the part of the road for a comparatively small outlay, together with the firm belief that such non-professional examinations, while frequently correct, were in no wise reliable, the manager being a good business man, as most railroad men are, quickly ordered the work to be done. The standard adopted was that a man should have at least a vision of 20-30 in one eye, should hear a watch tick at a distance of one foot and low conversation in at least one ear, and should not be color blind. The manager gave permission for defectives to wear glasses when they were capable of bringing vision to a satisfactory standard. This rule applies only to old employes and new applicants will have to pass a more rigid examination. The writer desires to emphasize the fact that all these men have passed the regular railroad examinations as to sight, hearing and color sense, and the results amply confirm the opinion that such examinations are totally superficial, unreliable, inadequate and dangerous. All men passed the aural examinations.

I submit the record of those having insufficient vision:

No. 1. E. D. V. R. E. = 20/60, with + 1.75 sph. V. = 20/20.

V. L. E. = 20/70, with + 2.25 sph. V. = 20/20.

No. 2. J. McG. V. R. E. = 20/40, with + 1.00 sph. C + 0.50 cyl. ax. 5° V. = 20/20.

V. L. E. = 20/40, with + 1.00 sph. C + 0.50 cyl. ax. 180° V. = 20/20.

No. 3. M. D. G. V. R. E. = 20/70. Iritic adhesions. No improvement with glasses.

V. L. E. = 20/40, with — 0.50 sph. C — 1.00 cyl. ax. 15° V. = 20/20.

No. 4. E. W. S. *Has been a locomotive engineer for twenty years.* V. R. E. = 20/100, with — 4.50 cyl. ax. 100° V. = 20/30.

V. L. E. = 20/200, with — 4.50 cyl. ax. 85° V. = 20/20.

He states that he sees as well now as he ever has, and the above glasses were simply a startling revelation to him. It is remarkable that he could have passed any kind of a previous examination and could have retained his position for so many years. He claims never to have had an accident attributable to poor vision. He must have been favored with good firemen to assist him in noticing signals, etc., and must have been a man of good judgment and blessed with unusual luck.

No. 5. M. B. V. R. E. = 20/100, with + 1.75 sph. C + 0.50 cyl. ax. 180° V. = 20/20.

V. L. E. = 20/100, with + 1.75 sph. \ominus + 0.50 cyl.
ax. 180° V. = 20/20.

No. 6. R. B. V. R. E. = 20/40.

V. L. E. = 20/30.

Mention is made of this case because he was under the writer's care in August, 1896, for tobacco amblyopia, at which time his vision was dimly 20-50 in each eye. He recovered with above result, but at this last examination he pledged himself to the superintendent and the writer that he would absolutely abstain from tobacco and intoxicants, and he retained employment upon this understanding.

No. 7. J. H. This man is color ignorant, and at first was thought to be color blind. After several days of instruction he was able to unerringly separate the worsteds; but it is difficult to understand how he passed the road examiner, for he puzzled four oculists.

No. 8. L. G. Distinctly color blind.

No. 9. D. N. B. Distinctly color blind.

It will therefore be seen that out of ninety men, eight defectives were found. No. 6, R. B., who had tobacco amblyopia, will not be so classed. Four men were fitted for their work with glasses. One man was educated in colors, and two men were unreservedly removed from their positions on account of unmistakable color blindness. The road has now directed their firemen to apply to the writer for examination, which is eminently proper, as they occupy important positions and are prospective engineers, and it would be a hardship to them to allow them to serve their apprenticeship with high hopes for the future, and then throw them out when they apply for an engineer's examination.

No.	MINNEAPOLIS, MINN.	189
I have this day examined	with the following result:	
Vision	Color Sense	Hearing
I would	recommend his employment as	
Remarks	FRANK ALLPORT, M.D.	

I submit the cards used in these tests, which are of a character to be easily understood by railroad authorities. The word "good" or "bad" is written after the words "vision," "color sense" and "hearing." The railroad authorities do not care to enter into any technicalities. They simply want to know if a man can pass the examination or not. The examiner can make all desirable observations in his private notebook, as they may be useful for future reference. There should be a space between the words "would" and "recommend," where the word "not" may be inserted if the applicant is deemed defective.

Stewart Building, State and Washington Streets.

DISCUSSION.

Dr. HERBERT HARLAN of Baltimore—There is not a great deal for me to say in regard to Dr. Allport's method of testing the eyes of school children because it is almost identical with the method he published a few years ago, and which Dr. Woods and I worked out independently about one year ago. I stated a year ago that as a result of our experience there were several objections to our method. One was that the blank that was sent to the parent by the teacher, after the vision of the child had been found to be less than 20/30, had a return blank to be filled by the oculist. They were rarely filled, and when they were, it was frequently by opticians and others, and so this year it was omitted. On the notice sent to the parents the wording was something like this: You are advised that this child's vision is below what the Board considers necessary to the proper performance of school duties, and you are advised to consult a physician who makes a specialty of eye diseases. This has been an improvement. The second objection was that last year the examinations were all made at the beginning of the school year, and within three or four weeks every dispensary was filled and it was absolutely impossible for any proper

refraction work to be done, so most of those children did not get the benefits they should have had. It has been arranged this year to distribute the work over the eight or nine months of school life. We also found it necessary to drop all the tests for the first grade, which contained all the younger children. We have records of 40,631 cases covering the other seven grades. Blanks were sent to all having less vision than 20/30 in the better eye. Many of them paid no attention to the notices last year, but the School Board holds that all it is required to do is to place the responsibility upon the parents. It has been shown, quite satisfactorily to me, that in some of the badly lighted schools vision has deteriorated within one year, and I think within five years we shall be able to show what this has been.

Dr. LEARTUS CONNOR of Detroit Stimulated no doubt by the researches of our friends in Philadelphia many years ago, and those in Minneapolis that have been reported to us, something has been done in many other places. In Detroit it took this form: The Board selected a person interested in child culture, to make the examinations. Those familiar with the latest phase of teaching know that there are people who think it proper also to study the physique of children and to encourage proper teaching in this direction. I think there should be hung over the top of the door of every schoolhouse, "Factory of American Citizens." This person told me last fall that in her own observations she had detected, out of 35,000 children, 3,000 who were unfit to do the work a child ought to do in school. Some could not see, some could not hear and others were defective in other ways. She came to me to see if something could not be done to help them, and as the Children's Free Hospital is organized for that purpose we did all we could. The principals of the several schools have organized a Mothers' League, and they give the mothers of the children, once a month in the schoolhouse, a lecture or demonstration by some physician or scientist. We never shall make progress until we can carry the mothers along with us in this work. The work in Philadelphia had its best fruition in bringing the parents to realize what they could and ought to do to help their children. One of the best contributions to modern medicine was that of Dr. Risley, who showed how correction of the early defects prevented the malignant troubles of later years.

Dr. S. D. RISLEY of Philadelphia—I have said so much on the subject it seems hardly necessary to rehearse the views I have so long entertained. I do feel like expressing the great gratification I feel on seeing this good missionary work being done in the schools. I regard it as of the greatest practical value. I agree with Dr. Allport that the examination must be made in such a way that no suspicion can attach as to any personal benefit to the doctor. If it does, the profession becomes sensitive about it and the family will think there is some ulterior purpose. I would say also that much the same plan as that suggested by Dr. Allport has been outlined in my article on school hygiene which is just about to appear. It is, I am sure, the correct plan.

Dr. G. EDGAR DEAN of Scranton, Pa.—I would call attention to one thing that has not been brought out; that is that the railroad men often while needing glasses do not wear them for the fear of incurring the displeasure of the railroad officials, and I have noticed repeatedly that they refrain from having their eyes examined on that account.

Dr. WILLIAM THOMSON—(Reading a note on the subject) In 1880 the Pennsylvania Railway adopted a complete system prepared by the writer to eliminate from the service men with poor vision, color blindness and deafness, which fully answered the purpose, is yet in use and has been widely copied by other roads. Its details are probably known to you, having been widely published. In the future the roads may be able to place all their examinations in the hands of professional experts who will improve upon the simple apparatus now in use, which supposes one ophthalmic surgeon only to superintend its application. It is believed that a brief report of the extent of the reform will be of interest. From 1880 to 1891 the example of the Pennsylvania Railway had been followed and their system adopted by twenty-four corporations, which controlled 38,786 miles of track; eleven companies, using other methods for detecting color blindness, controlled 15,679 miles; thirty-one companies, controlling 29,428 miles, used no tests, and thirty-four companies made no report. The investigation was limited to one hundred of the main roads, controlling 129,970 miles. The so-called color-stick had met with but one criticism, namely, that it was too formal in its arrangement of skeins. This led the writer to propose "A new wool test," described in the *Medical News* in August, 1891. This has been used with the older color-stick and from the best sources of information at hand I estimate that up to Jan. 1, 1897, when the total mileage of the country was 180,955 miles, and the

employees nearly a million in number, this entire system had been adopted by seventy eight corporations having under their control a total mileage of 106,395 miles of track. The publication of these facts may aid us in persuading the officers of roads now unprotected to adopt either this or some other system for disposing of dangerous employees.

Dr. G. E. SEAMAN of Milwaukee—I do not desire to discuss Dr. Allport's paper in a general way, but only to criticize briefly this card, which I understand is given to every pupil with defective vision. It would seem to me that in view of the spread of dispensary abuse in the cities this is a mistake. It would seem better, if this system is adopted, to take some pains to find out the financial standing of the people, and the teacher knowing the parties well might easily do this and give a card with the address of the dispensaries only to the very poor. If this card is given out to every one it will lead to more dispensary abuse.

Dr. C. D. WESTCOTT of Chicago. The dispensary abuse can be avoided, and the going to opticians also, by suggesting to the parents that they consult the family physician; he is the one I think should always advise in regard to consulting a specialist and the matter then becomes very simple.

Dr. E. E. HOLT of Portland, Me. — If the suggestion of the last speaker be adopted we should have to do some pioneer work among the family physicians.

Dr. ALLPORT—I have been much gratified by the commendation of the different members of the Section concerning this method of examining the eyes of school children. I have been especially glad to hear what Dr. Risley has to say upon the subject. The fact that he has probably had more to do with the personal examination of school children than any of us, adds especial significance to his endorsement of this plan.

The method which Dr. Risley adopted in Philadelphia some years ago was the *personal* examination of all school children in the city by *himself* or his *associates*. The plan which I advocate is the *preliminary* examination of all scholars (except those in first grade) by *school principals*, and then the sending of those deemed defective to competent authorities for further examination. I wish to distinctly emphasize two points: 1. That the method advocated in my paper is not perfect and can never be perfect. The fact that children are simply examined by a school principal and then, if found defective, sent to various sources for further examination, renders the accumulation of scientific data an utter impossibility. Defective children under this method are given a card of warning which they are to take to their parents, urging upon them the necessity of consultation with an oculist. Some of these children may go to a competent ophthalmologist, either at his office or dispensary; some may go to their family physician, who will undertake their treatment; some may go to an optician where they may receive ignorant or dishonest advice; others may go to a department store where worse conditions exist, and still others may not consult anybody. Under these divers and complicated conditions it will be manifestly seen, without further explanation, that the accumulation of scientific data will become an utter impossibility. 2. This method is not advocated for the accumulation of scientific data. It is advocated for the purpose of benefiting the coming generation, and I am perfectly satisfied that if the plan becomes generally adopted that, while subject to many criticisms, while being manifestly and necessarily imperfect, and while not facilitating the accumulation of scientific data, it will inevitably accomplish an enormous amount of good in these United States, and be the means of placing hundreds of thousands of children in better condition to face the various problems of life.

Dr. Harlan's blanks, which he presented at the Atlanta meeting, and has spoken of today, would undoubtedly be valuable if they could be followed up; but inasmuch as these defectives pass into the hands of a great variety of men, who may be friendly or unfriendly to the plan, or broad or jealous in their natures, it will be manifestly impossible to depend upon the different ophthalmologists and institutions in any city to fill out these blanks in a manner to make them at all valuable. Besides this, they are an additional burden upon the principals, who will be sufficiently burdened by the tests themselves and the rendering of the most primitive reports. It has been my aim to eliminate all forms of complication from this plan, and to make it as meager and simple as possible, hoping by this policy to secure its general adoption.

One of the gentlemen has objected to the printing of the names of the dispensaries upon the backs of the cards, fearing a congestion of charity patients. This course has been taken advisedly, after one year's experience. In the first place it is a great convenience to the principals and scholars, and in the second place it emphasizes the fact that free dispensaries are in existence, where people can get proper advice gratuitously,

which I am confident will greatly lessen the number of people seeking the advice of opticians. If the dispensaries suspect that individuals are not of the class that should patronize dispensaries, they can very easily eliminate them.

I hope that this ocular examination in schools will lead to tests for color blindness, deafness, and even more extensive physical examinations; but have desired first to secure the adoption of the plan referred to in my paper, and then gradually add to it other material.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

XX. — GUNSHOT WOUNDS, AMPUTATION, EXARTICULATION,
RESECTION.

(Concluded from p. 146.)

Let us return to the technique of *amputation* and place a knife in the hand of a German surgeon of the first and second halves of the century in order to learn the most customary methods of operation.

In Heister's time six assistants aided the operator, who girded himself with a "towel." A tourniquet was applied to the main artery and the nerves also compressed with it, in order to lessen the pain. The skin was drawn back as far as possible and a linen cord the breadth of the finger adjusted tightly around the limb somewhat above the point of operation that the muscles might be held together and not cut unevenly. When the patient had drunk a glass of wine or "Kraftwasser," the surgeon made a circular incision with a small knife through the skin and some of the muscles, had the skin drawn up still further and at its edge completed the circular incision with a large curved knife. On the forearm and leg a pointed two-edged knife separated the interosseous muscles. The periosteum was quickly pushed up, the musculature held back by a slit piece of linen and the bone sawed off as high as possible. On the large extremities the vessels were ligated or sutured, but it was thought that in the forearm the hemorrhage could be arrested by a piece of vitriol, a remedy, which indeed, along with the hot iron, was not widely disseminated on account of the pain and danger. Some considered ligature not generally necessary and awaited the closing of the vessels by the coagulated thrombus (Schaarschmidt). A bleeding was made either just before the amputation (Wreden) or, if little blood was lost by the operation, immediately after it (Z. Platner), or when severe inflammation ensued (Heister). The wound was bandaged with dry lint, a piece of puff-ball laid over that, then a fresh calf's or pig's bladder and several compresses. Only on the following day was the tourniquet loosened little by little and, provided no after-hemorrhage occurred, the first bandage was not removed before the fourth day. Later the wound was bound with digestive salve or balsam. At that time they amputated: 1. In case of mortification. 2. In entirely crushed limbs. 3. In incurable caries and spina ventosa. 4. In injuries of the art. brachialis and cruralis, if the hemorrhage could not be controlled. 5. In carious and deformed limbs as soon as they became painful.

In the second half of the century some surgeons bound a cord as tightly as possible around the limb just below and others just above the point where the amputation was to be made. An assistant laid upon the main artery a flattened linen roll and pressed it

close with both thumbs. This digital compression, introduced by Louis and adopted by Desault, Richter and the two Siebolds, was preferred to the tourniquet because the latter obstructed the free drawing back of the soft parts before sawing the bone. Instead of the curved sickle-like knife, which Schmucker, for example, still employed, the disadvantages of which Desault was one of the first to point out, the straight knife was used (Pott, B. Bell and Richter). The skin was cut by a special movement of the knife and afterward drawn backward as far as possible, and at its edge a circular incision was made in the muscles as far as the bone. The muscles were also drawn far upward by a slit compress of linen, parchment or leather, so that the bone could be sawed off as high as possible and its protrusion be prevented. The periosteum was cut but it was considered unnecessary to push it back; then the bone was sawed off and the large vessels bound up by means of artery pincers, the small ones with Bromfield hooks. (In regard to the arrest of the hemorrhage we refer to Chapter 14.) One sought first to report a healing by *prima intentio*, which method proceeded from the English surgeons and was introduced into Germany, especially by Richter. "The chief object of the surgeon in bandaging is to further the healing of the wound by a speedy union. The more the bandage serves this purpose and the simpler it is the better." For this purpose the double circular incision was the preferred method, because by it enough skin was preserved to cover the entire stump and prevent as far as possible the protrusion of the bone. The skin being drawn down was fastened by adhesive plaster laid crosswise, lint laid on that, a linen bag, "English cap," drawn tight over the stump to properly press together the lint and the skin. On both sides a thick compress was laid, which, held firm by a band, pressed the muscles together so that they could cohere; thus the wound formed a somewhat long fissure. By this method, as B. Bell and Richter applied it, a healing by *prima intentio* was indeed possible, but Bell said it came to pass only rarely and rather in private practice than in hospitals, and that it was the fault of this method to force a healing by sutures and too closely applied plasters. Surgeons soon became generally aware that any pressure exerted by the bandage injured, hence Desault adjusted it as gently as possible. Wardenburg also decried adhesive plasters and compresses, which acted very disadvantageously, and he would only use plaster to hold together the edges of the skin. Pouteau indeed discarded all bandages and left the stump to nature. The suture seemed to have fallen entirely into oblivion although Paré had known it and fastened the skin crosswise. Perhaps he had seen it in Italy, for Maggi, who wrote during Paré's time, mentioned this method quite clearly and said he had learned it from the executioners of Venice, who when they cut off the head of a criminal, brought down the skin previously drawn back, and sewed it around. Sharp and Bagieu again took up the suture. Bandaging was gradually further simplified and the many salves and bandages thrown aside. Larrey covered the stump with pure water with an occasional addition of wine or vinegar, although he could not justify healing by *prima intentio*, for he regarded it as reliable only in cases of amputations on account of injuries to healthful parts, but very pernicious after amputations on account of chronic diseases. Von Kern left the stump open without bandaging and

without suture, only cold applications by means of wet bath sponges or compresses were laid over the open surface of the wound during the first ten hours. Only if the wound was overlaid with plastic lymph he joined the edges of the stump with the greatest care by a few strips of adhesive plaster. If suppuration ensued, warm water was applied. Kern condemned the bandages, in use until then, because they kept the stump too warm and thus induced inflammation and suppuration, mechanically and chemically irritated the surface of the wound, and therefore for the most part prevented *prima intentio*, and the pressure of the adhesive plaster furthered the retraction of the soft parts. The effect of the atmosphere on the surface of the wound he regarded as not injurious, but on the contrary as useful. The results of Kern's experiments sounded very fortunate. In the second half of the century, according to B. Bell, the indications were as follows: 1. Complicated fractures, when the external conditions of the patient were bad, the fracture ran obliquely, the soft parts were much lacerated or in case of severe hemorrhage. 2. Large flesh wounds with laceration of the main artery. 3. A limb torn off by a cannon ball. 4. Mortification, when it became permanent. 5. White swelling in an advanced stage. 6. Sometimes in exostosis if it caused much pain. 7. Caries with extensive destruction of the soft parts, for without this one might remove the carious bone alone. 8. Cancer. 9. Various tumors which might destroy the soft parts and bone by continued pressure. 10. Stiff and crippled limbs when they cause the patient much suffering.

Until the beginning of the eighteenth century the single circular incision, according to Celsus, was in use; hence, for more than fifteen hundred years it was the only method. The simple flap incision, which Lowdham of Oxford devised for the leg, and imparted in a letter to Young, who published the method (1679) and which was then described by Verduin of Amsterdam (1696), had only just appeared. It was seen that the danger in amputation was very much reduced if the wound was made as small as possible, so that it healed quickly by *prima intentio*, and suppuration would be entirely or mostly avoided if the protrusion of the bone could be prevented and a thick cushion of flesh retained. With this object various methods were suggested: the circular incision made at two different times by Cheselden and J. L. Petit, the double-flap incision by Ravaton and Vermale, funnel incision by Alanson.

J. L. Petit especially deserves the credit of the *double circular incision*. Proceeding from the principle that only the skin was adapted to a quick junction and the preservation of the muscles affords no essential advantages for the covering of the stump of the bone, he cut through the skin at a deeper point, then when it had been pushed back, cut through the muscles at its edge and drew these up with a slit band. To pare off the periosteum before sawing he did not consider necessary. Louis allowed the protrusion of the bone to depend upon the contraction of the muscles, and therefore enveloped the limb from above downward. This circular bandage came very much into use, but was rejected by some surgeons because it hindered the return flow of the blood, and if it was to be used with success had to be too tightly applied (Richter). The cutting through of the muscles was done in various ways; now with one stroke (Louis), again in layers (Desault); either with extreme relax-

ation of the limb (Portal) or in extreme extension (Valentin). In both ways it was sought to avoid a protrusion of the bone. The covering of the stump by a simple flap of skin was recommended, especially by J. L. Petit, Kirkland and Brünninghausen.

Verduin's *simple flap incision* from within outward found many opponents (Heister, Z. Platner, la Faye and Sharp); on the other hand, the *double flap incision* found many advocates. Ravaton began four inches under the point where the bone was to be sawed through with a circular incision through the soft parts, and by incisions from without inward formed two four-cornered flaps. Vermale discontinued the circular incision and formed the lobes by two incisions from within outward. The double flap incision was in the beginning very favorably received in France, but was later pushed into the background by the double circular incision which the English surgeons, and especially Larrey, recommended. Desault, Pott and C. C. von Siebold secured with it very successful results; Richter, also, for the upper thigh, preferred a double flap to all other methods.

Alanson of Liverpool (Pract. obs. on amputation, 1779) invented the *funnel incision*. After a circular incision through the skin the knife was passed upward and inward and in this direction around the limb so that the wound received the form of a funnel and its point fell where the bone was to be sawed off. This was an unlucky proposition which found almost no endorsement. Loder was one of the few to praise certain features of this method, while the French surgeons as well as B. Bell and Richter rejected it entirely. The last named called it a fancy of the study (stubeneinfall) as it was not at all possible to make the above described incision.

We must yet notice the *bloodless amputation*, a discovery of Guy de Chauliac, who enveloped the whole limb with pitch plaster and so laced it at the joint that it finally fell off. The Austrian surgeon, Wrabetz, gave a new procedure for this operation (1782). How atrocious it was is shown by the following description: "I had the skin around the healthy part drawn back, bound a cord around the sound portion four fingers' breadth above the elbow, which cord had lain twelve hours in a mixture of spirits of turpentine, tobacco leaves, rue, Spanish fly and camphor, and twisted it with a short stick, applied upon it the mixture in which it had lain, spreading it over the cord upon the arm, along the artery, but applying and fastening a rather long pad in order to obstruct the inflow of the blood. The cord I had twisted more from time to time and in the furrow which it made in the flesh I had a powder of cinchona, myrrh, camphor and alum strewn. The fourth day all the soft parts were separated down to the bone without the least flow of blood, whereupon I sawed off the bone. The stump was healed in five weeks." Wrabetz in this way bound off fingers, toes, hands and feet with success, and Ploucquet of Tübingen recommended it in case of thin and timid people.

The *low amputation of the lower leg* claimed an especial interest. They were accustomed always to cut it off three fingers below the knee, even if the ailment was limited to the foot, because they considered a long stump inconvenient and did not believe an artificial leg could be applied. Paré had entirely discarded the low amputation and relates the story of a captain who, after he had recovered from it again

had his leg amputated in the calf because the stump was too burdensome to him. Even at the end of the seventeenth century Solingen and Dionis advised this amputation and Garengeot asserted that the long stump was no hindrance at all. The practice was, however, entirely forgotten. The first who again showed the practical possibility of this method appears to have been Ravaton (*Journ. de Nandermonne*, vi, p. 130, 1756), without, however, having discovered it as he believed. He made several amputations of this kind and argued as its advantages the slight danger, the smallness and quick healing of the wound and the small number of the large blood vessels and nerves, and asserted that with two flaps the operation was very easy. With his artificial leg devised for this purpose the patient could walk conveniently; indeed, one upon whom he had operated made three campaigns afterward. After him Trecourt ("Mém. de Chir.," 1769, p. 256) and especially Charles White ("Cases in Surgery," 1770) came for this operation, with which the latter had several successful results to show. He advised as low an amputation as possible always by means of the lobed incision, but would fasten the lobes upon the stump with court plaster when after some fourteen days the suppuration was in progress and the bones had covered themselves with granulations. He also constructed for the purpose a boot-like apparatus. Since that the low amputation has become established in surgery. On the other hand, if it were a question of amputation just under the knee, some would not amputate at this point but above the knee, because shattering of the bone and caries might possibly extend into the joint, and besides the artificial leg would have a better hold on the thigh (B. Bell and Richter).

Artificial limbs had already been devised by Paré, Fabr. v. Hilden and Solingen. Heister spoke of wooden and silver limbs, which "had been very curiously devised by various mechanics." Besides the above mentioned, one known in Germany as the best was that of Brünninghausen for the high amputation of the thigh. This consisted of a calf made of copper, a heel, middle foot and toe-piece, which were fashioned out of light but firm wood by a sculptor, exactly after the sound foot.

There prevailed a great horror of *exarticulation*. Performed by Fabr. von Hilden, Paré and other older surgeons, and not entirely rejected by Heister and J. L. Petit, in the middle of the century, they had fallen very much out of use. Brasdor, le Blanc, Sabatier, Larrey and others sought to allay the loudly expressed terror and argued that the dangers would be entirely avoided if one cut entirely through the sinewy parts, and that the bone exfoliated slightly and soon became covered with granulation. They considered exarticulation as easily practicable and warmly recommended it.

The second birth of these operations began with the exarticulation of the *upper arm*. This was first done by Morand, senior (1710), then by le Dran and improved by la Faye (1740). In caries and inflammation Heister would never have the large limbs taken out at the joints, but still he exhaustively described le Dran's operation. Later Bromfield and Desault performed this exarticulation with success, and Larrey introduced it into military surgery. Almost every one of these surgeons had his own methods. The circular incision was soon superseded by the lobed incision; Morand, Garengeot, Sharp and Alanson operated with the former. In order to the more easily control

the hemorrhage, la Faye devised the flap incision, which either with forward and backward, or with outer and inner flaps was adopted by Bromfield, Desault, B. Bell and Larrey, and is still practiced. Later Larrey devised the oval method. It was the hemorrhage chiefly which gave rise to the many modifications in the methods. Morand punctured the axillaris subcutaneously with a curved needle and bound the provisional ligature over a compress in the axillary cavity: he then exarticulated it, bound the artery definitely and released the provisional ligature. Le Dran recommended that the artery, before the operation, be punctured in the axillary cavity; la Faye advised the continuous binding of the axillaris before the formation of the two flaps. The essential improvement, which controlled the hemorrhages, was the method of Poyet (1759) who, before the cutting of the second flap, which contained the artery, had an assistant reach into the wound and compress the flap. This manual compression, already in use by Desault, has continued to the present day. Bromfield also deserves the credit for compressing the subclavia against the first rib with the finger instead of with the tourniquet, a method which soon found general acceptance and superseded the legion of inconvenient tourniquets constructed especially for that purpose. The technique was extraordinarily varied; some would bind the blood vessels as high up as possible, others as low as possible, so that the flaps would be sufficiently nourished through the side branches; one pared the cartilage of the socket off, another did not because the soft parts united with the cartilage as readily as with the bones. The indications for exarticulation humeri were caries and shattering of the bone, in consequence of a shot (Alanson with success, 1779). Soon, however, the operation experienced a limitation, since, when the soft parts were affected slightly or not at all, the resection of the head of the humerus was substituted. The exarticulation of the *elbow joint* first made by Paré (1536) and afterward by a Brandenburg surgeon, Chr. Rumph-tun (1671) was somewhat outside the usual course. Now it was recommended again (Brasdor and Richter): but it was stated against it that the stump had not a sufficient cushion of flesh, and in the aponeurotic parts a good suppuration never arose (Schmucker). Exarticulation of the hand joint, which it appears was first accomplished by Fabr. v. Hilden, and indeed with the circular incision, was very rare. Heister never made it nor saw it made, and Z. Platner does not mention it at all. Later, in France, it found acceptance, where Sabatier and others performed it with success. On the other hand, *fingers and toes* were exarticulated with the greatest partiality, and it was advised that the cartilage be cut through in order to shorten the time of the cure.

The bold idea of exarticulation of the shoulder joint was scarcely sketched out and a few successful cures heard of when courageous surgeons found the exarticulation of the *hip joint* suggested, an operation which demanded the greatest care. The Danish military surgeon Wohler and the Swiss Puthod, both pupils of Morand, had first expressed the idea of this operation, had tried it with their teacher on a cadaver, and in 1739 submitted their proposition to the Académie de chirurgie. Le Dran and Guérin rendered a favorable judgment. Later Lalouette wrote on the subject; he did not consider the operation absolutely dangerous, as the art. iliaca could be compressed, and

in his experiments on cadavers, scarcely twelve ounces of the water injected into the aorta flowed out of the severed artery of the thigh. Then Ravaton wished to carry out the exarticulation upon a living person, but was restrained by the consulting surgeons. When the Academy upon the suggestion of Morand, in 1754 called for prize essays on the indications and best technique, among forty-four works submitted, there were thirty which held the operation to be possible. The marine physician, Barbet, received the prize, expressing himself in favor of the operation in case of shattered bones and caries of the neck and head of the femur, and in aneurysm and gangrene. This impelled Morand to make known the work of his two pupils (1768) and to recommend the operation in case of shattering and caries, where it must be regarded as the only way of saving from death. He sought to meet the charge of cruelty and of enormously large wounds and hemorrhages, and argued that the operation had been performed successfully upon three dogs and two sheep. Among the surgeons who championed the operation was, strangely enough, the conservative Bilguer. But he, as well as his translator Tissot, preferred exarticulation to the amputation of the upper thigh. The former indeed recognized the great difficulties, but would in that way avoid the inconveniences of a stump; the latter, from his student's chamber had arrived at the conclusion that the hemorrhage could be more readily stilled in articulation. Pott combatted these views in so far that, although he admitted the possibility of the operation, which he himself had never performed but had seen performed, he however expressed the safe conviction that he would never perform it, because in most cases of caries of the head of the femur the cavity of the joint was also carious. When Schmucker had become acquainted with the difficulties of the operation on cadavers and in cases of fracture, he thought that hardly anybody would be bold enough to carry out the operation, called it the most cruel in all surgery, one which nobody would recover from, and one compared with which Cæsarean section itself was but a trifle.

B. Bell and Richter could not coincide with these entirely dogmatic views. Indeed they did not ignore the dangers, but believed that by the formation of two flaps as the former suggested, they could be overcome, in which way the arteries would be severed deep down, where their diameter was less and a healing by *prima intentio* could be attempted. For Bell a chief difficulty consisted in the uncertain diagnosis, as one could not know whether the caries extended also to the cavity and pelvic bones, so that the operation might probably result fatally. Besides, if the soft parts were affected slightly or not at all it might be avoided by the resection of the head of the femur, while in case of the destruction of the soft parts the exhaustion of the patient might make success very doubtful. To Richter the exarticulation was very seldom unavoidably necessary. Later Sabatier argued that it caused less pain and occasioned a smaller wound surface than amputation. It is not exactly known who first carried out the exarticulation on a living person, whether Henry Thompson or Per-rault, in 1770. The French gave Lacroix the honor; but his operation (1748) performed on a 14 year old girl for gangrene consisted only in a few shears-cuts to sever the extremity; the patient died on the eleventh day. In 1779 Kerr of Northampton oper-

ated upon a girl, who died on the eighteenth day in consequence of pelvic suppuration. Larrey first made the exarticulation in the field, and indeed made it eight times with success, during his twenty-five campaigns.

The exarticulation of the *knee joint* was mentioned by Fabr. von Hilden as a common operation, was discarded by Dionis and performed by J. L. Petit twice with success, and without the occurrence of ill consequences. Brasdor (1774) sought to introduce it again. He considered amputation of the upper thigh in the larger wounds as more dangerous, and did not fear caries of the naked joint surface because the cartilage soon became covered with granulations; he lauded the easy accomplishment and the slight pain of the exarticulation. He recommended the formation of a posterior flap and the sparing of the patella. While Richter recognized the arguments of Brasdor, Schmucker ruled against the exarticulation for the same reasons as in the case of the elbow joint. It did not meet with acceptance at that time. The exarticulation of the *astragalus*, which Sédillier had accomplished without ill consequences, and with quick healing of the wound (1774), also found no approval although Brasdor and Sabatier submitted special methods for it. Amputation above the tarsal bones was preferred. The exarticulation of the *tarsal joint*, the possibility of which von Abbeville demonstrated (1746), was also mentioned by Heister; "the surgeons of today are accustomed in case of a diseased foot to amputate it at the joint with a knife, to separate the toes from the metatarsus, or the metatarsus from the tarsus, or ossa tarsi from each other, so that one could go about again, somewhat, upon the foot as upon a crutch." Its first accomplishment became known through Hunczovsky, who in 1780 when with du Vivier in Rochefort, saw an 8 year old boy whose foot had been severed at the joint for caries, the talus and calcaneum being left. Two months later the patient began to walk comfortably. The operation was forgotten until Chopart took it up anew. He performed it in 1791 and described the practice which has since borne his name. He was followed by Lafiteau and M. A. Petit, the latter of whom observed a retraction of the heel which rendered walking entirely impossible so that he decided upon severing the tendon of Achilles (1799). The exarticulation of all the *bones of the metatarsus*, pointed out by Garengot and Heister, was first performed by Percy (1789) and was later introduced into practice by Lisfranc (1815).

To the ingenious ideas which were conceived in the foregoing century belongs *joint resection*. Like most great discoveries, this also had its precursors which consisted in the removal of the ends of dislocated joints and in the extraction of necrotic or splintered pieces of bone. It is not without interest to observe how within the space of a few years the beginnings of a conservative surgery converged from two different sides. To save limbs and avoid mutilating operations was the aim, but the ways differed. In the year 1761 Bilguer came forward with his conservative treatment. In 1768 Charles White of Manchester, gave the first impetus to joint resection with his now celebrated operation. With it he desired to avoid amputation and exarticulation in many cases, if not to entirely supersede them, as was Bilguer's wish. A 14 year old boy contracted an acute osteomyelitis of the arm, in consequence of which the head of the humerus became necrotic. Ichorous pus, diarrhea and

fever had enfeebled the patient to the last degree. Instead of exarticulating the arm, which must have been regarded at that time as the only means of saving the patient, White opened the joint with a single large, longitudinal incision, extending to the middle of the arm, and removed the loosened necrotic head of the upper arm. Improvement began immediately and six weeks later an unexpected firmness was found in the joint. Soon thereafter a piece of the diaphysis separated itself so that from the upper end of the humerus a piece five inches long was lost. The arm was lightly bound without splints or other bandages; indeed, the patient sat in a chair during almost the whole treatment. Perfect recovery ensued and the replacement of the bone was so complete that the arm was only an inch shorter than the sound one and moved freely and could be not only lifted but also rotated. White said, "I think I may safely say, the head, neck, and part of the body of the os humeri are actually regenerated" ("Cases in surgery," 1770; "Philosoph. Transact.," vol. 59 for the year 1769, London, 1770).

The advantages of this operation, through which the exarticulation of the upper arm could frequently be avoided, were too brilliant for his contemporaries to be able to overlook them. In Germany they soon became aware of the great value of this operation. When Richter became acquainted with White's work, shortly after its achievement, he recommended that resection be made as soon as the soft parts had suffered slightly. And the first one who repeated the resection, and indeed on the upper arm, was a German, Lentin. He performed it in 1771 in case of a 14 year old girl for caries, removed at one time almost the whole diaphysis of the humerus, and as a result of bone regeneration restored the use of the arm with limited mobility. Soon E. Platner recommended this operation in case of caries. Foreign countries followed. The Englishmen, Bent and Orred in the seventies performed the resection of the head of the upper arm; the former used the longitudinal incision with two other transverse incisions; the latter, in order to spare the artery, placed a piece of pasteboard under the bone before he sawed it off. The piece which had been removed was replaced by callus and after three months the arm could be moved in all directions without hindrance. In France Sabatier and the elder Moreau especially took an interest in this resection; the latter formed the four-cornered lobe. Percy and Larrey enriched military surgery with it. The latter as early as 1795 was enabled to report to his colleague, Sabatier, nine soldiers for whom the resection of the shoulder joint had been performed by him; Larrey made this operation ten times in Egypt.

If joint resection did not become established as soon as had been expected, this was due to several obstacles: 1. The experiments in France on animals, which were conducted by Chaussier and Vermandois, did not succeed because they spared neither periosteum nor joint capsule. 2. Many surgeons regarded joint resection as equivalent to *resection of the bones where continuous*. This was frequently brought into use in complicated and gunshot fractures, caries, necrosis and pseudo-arthritis. We have already mentioned that the military surgeons, Bilguer and Theden, also Percy and Larrey in gunshot fractures, frequently laid bare the broken place by large incisions and resected the sharp ends successfully. Large pieces of bone were

fearlessly removed. A. F. Vogel sawed one and one-half inches from both ends of the broken bone, whereupon the arm, without shortening, grew so as to be used; le Cat sawed off three inches; indeed Siegwart of Tübingen removed an entire carious tibia (1770), which became completely regenerated. While W. Hey could also show successes relative to this bone, Moreau, senior, did not succeed in the resection of long carious bones on account of failure of regeneration. Partial resection of the ribs, known even in antiquity, was not infrequent in case of caries (Gooch, Acrel and Percy).

If we turn back to joint resection we find that the next advancement, after White, was made by H. Park, Liverpool. He was acquainted with the operations of his countrymen and made the hitherto unheard of proposition to entirely eradicate the joint, i. e., the whole of the abutting bone ends, and to remove the whole joint capsule or the greater part of it. In this way in tumor albus, suppuration of joints and complicated shot fractures amputation could be avoided and the loss of the extremity prevented. Park's work in the shape of a letter to Percival Pott, dated Sept. 18, 1782, an account of a new method of treating diseases of the joints of the knee and elbow (1783), is surpassingly well written, and is simple and practical. All the objections which could be urged against this method Park believed he was able to overcome, since they were only apparent. The large blood vessels could be avoided readily in the arm as well as in the knee; a violent inflammation was less to be feared in large wounds where all the parts were completely cut through. That a sufficiently firm callus would develop was, after experience in complicated fractures, not to be doubted; on the other hand, the loss of the extensor muscles was of no importance as the limb became ankylosed. Walking with a stiff shortened leg was safe enough and amputation afforded no better chance of removing all disease and preventing relapse. The investigations of Park were limited to the knee and elbow joints. In his experiment on cadavers he made only a longitudinal incision in the knee joint, which White had already established as a principle in case of a shoulder joint and found it sufficient, but had in general difficulty in making it serve. In his first resection of the *knee joint* made on a sailor thirty years old, for caries (July 2, 1781), Park began with a single longitudinal incision, but after several fruitless experiments found a transverse incision necessary, which he made from the middle over the patella. After carefully removing the knee capsule a spatula was applied behind the bone to protect the large blood vessels from the saw. The piece resected from the femur was two inches long; that from the tibia, one inch long. In order to hold the bones close together they laid the limb in metallic splints, stitched the skin together and bandaged it but slightly. A violent, bad smelling suppuration ensued for which a pulp of turnip was applied and cinchona given internally; the fever remained moderate. After four weeks a partially osseous union existed. In its later course several abscesses must be opened. After nine months the bones were firmly united and the wounds healed. The patient walked without crutches with one limb three inches shorter than the other, wore a shoe with a high heel and later went to sea again. Park was well aware that the cure always took a long time and that the operation would not always succeed. (His second knee-joint

resection in 1789 proved fatal after four months); therefore he hesitated about suggesting it in the large hospitals of London where complicated fractures were so seldom cured. But amputation also frequently resulted fatally; however, resection which has better chances in injuries than in diseases from internal causes should never supersede amputation, for the latter always deserves the preference where the soft parts have suffered severely or the bone disease has extended far upward.

Park's operation, through which the resection of the knee joint with the presentation of certain indications and a systematic technique, was introduced in surgery (for Filkin of Norwich, who had performed this resection with success in 1762, first published it later), found favorable acceptance. B. Bell endorsed it, although experience must first teach whether the method deserved a general application. It would always remain difficult to prevent the accumulation of pus, the generation of fistulae, and to fix the limb properly. For this purpose Richter would maintain the limb in a straight position as well as extended and placed no importance upon the shortening. In spite of everything the Frenchman, Lancelot-Haine, pronounced a thoroughly depreciative judgment upon Park's resection, regarded it as very difficult and horrible and said that after much pain, trouble and danger a newly acquired stiff bone was less useful than an artificial one (1787). The resection of the knee joint was first repeated by Moreau, senior, in case of caries (1792). To partial resection might belong the extirpation of the patella, which Theden made in case of a shot fracture, but the patient died of gangrene.

Gradually resection was applied to other joints and ankylosis was regarded as the most favorable result. The greatest credit for its wider development is due to Moreau, senior, who operated upon various joints, in the 80's and 90's, and communicated his experiences to the Académie de Chirurgie (1789). Unfortunately, this body, ruled by prejudice and influenced by Chaussier's unfavorable experiments, showed no interest in one of the most valuable achievements of surgery. Moreau did not allow himself to be terrified; he perfected the technique and operated in his private practice, while the great Parisian hospital surgeons remained indifferent. Moreau, the son, followed in the footsteps of his father and in the Académie de Médecine had the same melancholy experiences. Nevertheless the outcast child of Sabatier, Percy, Larrey and Ph. Roux was sheltered and nursed. In the year 1812 Percy wrote that the number of joint resections accomplished by him, Larrey and other French military surgeons was already so great that one could not count the cases. Above all others the English surgeons should have been interested in the discovery of their countryman; they remained indifferent. So the flowering time of joint resections only began in our century.

Extraction of splinters from the *elbow joint* in gunshot fractures, and a partial resection, which consisted in sawing off the humerus condyles in a complicated luxation (Wainmann, 1758), had taken place, when Park proposed the total joint resection. Here he considered a longitudinal incision as not sufficient and a crucial incision necessary. If he himself did not carry out the operation yet he recommended it, as his much more difficult resection of the knee joint had succeeded. After Görcke in a shot wound had successfully made a partial resection by removing the

head of the ulna (1793) and Bilguer had resected the olecranon, Moreau, senior, first performed the total resection in a case of caries in 1794. He made an H-shaped incision, took one inch off each of the three bones and after seven months obtained a cure. He repeated the operation several times and found a follower in Percy, who first accomplished the total resection in a gunshot fracture. The honor of first making an experiment in resection of the wrist, belongs to the Prussian staff physician Beyer. As Bilguer relates, Beyer in 1762, at the battle of Freiburg, removed both under epiphyses of the forearm bones and the ends of the ossa carpi and metacarpi from a wounded soldier's hand, shattered by a howitzer. The hand indeed did not again become so as to be used, and the operation was not a methodic resection; but if it were correctly performed, it deserved to be imitated, as an immobile hand is always better than the stump of an amputated forearm.

The resection of the *hip joint* was proposed by Charles White in 1769 and practiced on cadavers; yet a half century passed before it was carried out on living persons. Verandois and Koeler of Göttingen, undertook experiments on animals and endeavored to determine the possibility of the operation and its results. Observation at the bedside also contributed to that end. It was seen that in the last stage of coxitis, in case of long standing caries of the head of the femur, this might become loosened naturally, and after its artificial removal a cure might result. Schlichting (1730) after the outbreak of pus and the previous enlargement of the fistula, had removed the whole head; the wound healed after six weeks and the girl could walk again. A. F. Vogel also (1771) in a suppurating of the hip joint removed the bad-smelling pus and found the head of the femur sundered from the neck. The diaphysis with the neck lay upon the oval cavity, where it was allowed to remain and cicatrize. After three months, recovery ensued; the patient could walk about, limping, but without a cane. Fear of the difficulty of the operation may for a long time have prevented its perfect fulfilment; for only in the year 1817 a German physician, Schmalz of Pirna, first applied the knife to the resection. He would indeed have carried it out but found that nature had already sundered the carious neck of the femur so that he needed only to grasp it and draw it out with the hand. In truth, Anthony White of London was the first who carried out the operation, in 1821; he resected four inches of carious femur and accomplished a cure with great mobility and slight shortening of the limb. Oppenheim performed it in 1829 in the Russo-Turkish war; first in a gunshot injury. If we except the removal of luxated or fractured parts of the ankle, which had in all times been performed (by W. Hey, and Kirkland, on both lower leg bones, by Gooch on the tibia, etc.), then the history of the total resection of the *ankle* began in 1792 when it was successfully accomplished by Rumsey in a complicated luxation with fracture of the astragalus, and by Moreau, senior, in case of caries. The resection of one or more tarsal bones did no longer belong among rarities (Moreau, Desault, Hey, Bilguer and others).

Finally resections of the *jaw*.—Partial removal of a part of the *upper jaw* was accomplished on account of carcinoma (Gensoul); sarcoma and exostosis (Desault). Among those of the *lower jaw* was the excarticulation of one-half of the bone, in the last century, which operation the Austrian military surgeon Fischer

first performed in 1793 in a shot wound. A large incision through the masseter and the parotid exposed the proc. condyloideus and coronoideus; the joint cavity was opened and the entire left half of the lower jaw removed, whereupon healing followed. In closing, a remembrance to a German surgeon and namesake!

THE END.

[ERRATA.—In the JOURNAL for March 13, 1897, page 494, second column, nineteenth line from the bottom, the word "peritoneum" should read "perineum;" also, in the JOURNAL for July 31, 1897, page 234, first column, fifteenth line from top, the word "anterior" should read "posterior."]

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

A regular meeting was held Nov. 12, 1897, with Dr. A. E. BALDWIN in the Chair.

Dr. R. B. PREBLE read a paper entitled

GASTRECTASIS, WITH A TETANOID CONDITION AND THE SO CALLED PULMONARY HYPERTROPHIC OSTEO-ARTHRITIS OF MARIE.

The case upon which the paper is based is that of a Pole, a male of 32 years, free from all hereditary taints, bad habits and venereal infection. For past six months has complained of eructations, nausea, vomiting, attacks of diarrhea, anorexia, loss of strength and emaciation.

Physical examination of chest negative. Abdomen full and distended, especially in the epigastric region. Marked succussion over stomach. Distention of stomach with gas shows it to extend from normal borders above to hand breadth below umbilicus and far to the right. Urine negative. Temperature of 101 once. The distal phalanges of the hands very much thickened; typical clubbed fingers. A week later returned with tonic spasm of the masseters, the flexors of forearm, wrist and fingers. Arms held against chest, elbows at right angles, thumbs adducted, the fingers flexed in all joints, i.e., an almost but not quite typical spasm of tetany. Reflexes exaggerated, sensation normal, Chvostek and Trousseau signs absent. Has had such spasms at intervals for some time.

The clinical diagnosis made was gastrectasis, with the so-called pulmonary hypertrophic osteo arthritis of Marie and with a tetanoid condition. The association of gastrectasis with true tetany is rare, with incomplete tetany or tetanoid condition more common. The common theories of the etiology of tetany were reviewed, especial attention being given to that of auto-intoxication. The efforts of various experimenters to discover the causal toxins in the gastric contents and their failures so far were reviewed. Gumprecht failed in a recent case to discover any peculiar toxic bodies in the urine of such a case. The urine, however, showed twice the normal toxicity. The clubbing of the fingers, in the absence of any other demonstrable lesion, was referred to the gastrectasis. The popular explanation of this condition is, that it is due to the action of absorbed toxins upon the bones. The source of these poisons is oftenest a bronchiectasis or empyema, but they may be absorbed from other places as cysto-pyelonephritis, the intestines in dysentery. This case is the first example where the source of the toxins seemed to be the stagnating contents of a gastrectasis. An X-ray photograph showed that the bulk of the thickening was in the soft parts rather than in the bones. The bones, however, showed some excrescences and were also more transparent than normal, probably the result of a rarefying osteitis, such as is often seen in this condition.

The case is of interest because it shows in one individual two conditions of uncertain etiology, both of which are generally believed to be due to an auto-intoxication of the organism with toxins. Secondly, it would seem to be a connecting link between rachitis, a nutritional disturbance in which the bones are affected and which is often accompanied by tetany and the tetany of adults, which until now has not been seen in association with osteal changes, apparently due to the condition which caused the tetany.

DISCUSSION.

Dr. FENTON B. TURCK—There are some objections to the word tetany as used in these cases. It is to be borne in mind that some of these patients have exhibited signs of tetany and have at other times manifested almost the epileptic form of convulsions. I wish to present tonight the reason, so far as my observation goes, of what I believe to be the cause of this

disease, and also to report two or three interesting cases in my own experience. In all cases of true gastrectasis we will find a marked atony of the stomach with hypertrophy of the pyloric orifice. In other words, we have obstruction of the pylorus *plus* atony of the stomach wall. In other cases we have primary hypertrophy of the pylorus when compensation occurs, the wall becomes thicker and stronger, but subsequently results in true dilatation. The pathology of true dilatation is markedly different in many of these cases. The round cell infiltration that occurs produces the true dilatation. The round cell infiltration, resulting in atrophy, usually begins in the glandular area and extends into the muscular tissue, this condition necessarily causing retention and stagnation. The micro-organisms already present there have abundant opportunity to develop, resulting in putrefactive decomposition and fermentation. These toxic products, whether we have tetany or not, found in a patient's stomach, will produce tetanic convulsions when injected into animals. Evidence derived from frequent experiments I have made, leads me to conclude that in many of these conditions we can prove a toxic condition of the stomach contents. I have made a series of experiments on the stomachs of soldiers in the regular army, in the normal condition, and have compared them with various cases of dilatation and retention, which show decided hypertoxicity of the stomach contents. In these cases there is another condition to which I would call attention, namely, starvation. It will be remembered that Van Gieson referred to this starvation as being a form of intoxication, and that we have coupled with this a lowered vitality and resistance to the action of the poisons, which is the second condition that must be considered. A third condition which I wish to call attention to in this class of patients which I have observed is that there is usually a "neurotic tendency." The patients themselves have not the inhibitory power that we find in other patients manifesting similar conditions of gastric dilatation. I mention these three factors to be considered as relating to tetany.

A word or two as to diagnosis. The method that has been heretofore practiced is simply that of outlining the organ by the use of gas or air introduced into the stomach. This is faulty from the fact that the gas or air will frequently pass into the intestines, and percussion will show the stomach as if located further down or to the right than would be shown by direct methods. The use of the electric light (Einhorn's method) is valuable in the hands of an expert, but it is impracticable for general practice. We know that the use of the gyromele (revolving sound) affords us exact evidence of the size and location of the stomach in every case.

I wish now to report a case that was referred to me by Dr. C. S. Bacon in 1893, in which I found hypertrophy and stenosis of the pylorus with marked dilatation of the stomach and stagnation. On examining the stomach contents I secured 800 c.c. of fluid. A peculiarity of these cases, which is often noted, is that upon the introduction of a stomach tube a convulsion sometimes follows. In this case there was no convulsion after passing the tube until the patient had returned home, when I found him in a condition simulating opisthotonus. I found contraction of the jaws, the arms flexed upon the breast, and in this rigid condition the patient seemed to breathe heavily, the pulse was rapid and the temperature 101.5 degrees. Subsequently he had two or three lighter attacks, but following the tetany the attacks became more epileptiform in character. The patient was treated for a while and compensation occurred, *i. e.*, the stomach wall became thicker and stronger and the food passed out of the stomach into the intestines normally and in time, and the symptoms disappeared. But some time after the symptoms reappeared and it was decided to do a pyloroplasty operation. The Heineke-Mikulicz operation was performed and from that time the symptoms entirely disappeared.

The second case was one which resembled the first in some of its manifestations and was sent to me by Drs. Ferguson and Sanger Brown. Mrs. S. had had more or less epileptic attacks, but there was a peculiar form of tetany in this case which occurred in the abdominal muscles. A clonic spasm would make its appearance and then was followed by a tetanic spasm until contractions occurred so markedly as to extend to the arms and involve the jaws. The peculiarity in this case was that the symptoms began in the abdominal muscles.

A third case was sent to me by Dr. Cuthbertson and was that of a woman who had hyperemesis of pregnancy and the patient had had a previous history of two or three attacks during which she could not open her jaws. In her case there were mild periodic attacks of tetany. She was treated and we found such a large mass of sarcina that the other physicians thought it was pus. I withdrew something like two liters in two days. The patient, after being observed a week, had an attack of tetany which commenced with difficulty in swallow-

ing, at 3 o'clock in the afternoon; at 5 o'clock the jaws were closed, at 6 arms were involved, and then the legs, and at 9 she died from tetany. In the meantime I brought with me tetanus antitoxin, thinking it would have some effect on the tetany, but it produced no effect.

There is one point I wish to mention, and that is, in most cases associated with gastric tetany there is either a total obstruction or the pylorus is so narrow that material can not be forced into the intestines. In all cases of this character we should advise operative interference at once and perform the Heineke-Mikulicz pyloroplasty operation.

Dr. JAMES C. KIERNAN—In dealing with these conditions the two hypotheses can very well be combined that have been advanced by Dr. Preble and Dr. Turck. There are few cases, especially among the conditions hinted at by Dr. Preble, in which neurasthenia with its consequence and its gastric expression is unlikely to occur. Dr. Turck has hinted at a large number of cases being neurotic. The last case which he reported was, I think, one of puerperal tetanus and not tetany, as I understand the term. The condition of tetany is by no means rare, as Dr. Preble has remarked, in children, not merely with reference to rickets, but with regard to an expression of both nerve tire and irregular nutrition which is recognized now to a considerable extent as one of the underlying factors of scurvy. The conditions which today are placed under scurvy of the infant and charged to diet were some years back charged to innutrition, many of them being placed under the condition known as pilosis rheumatica nodosum, whose dermic lesions resembled the ecchymoses. In many of the cases the true condition known as tetany, or, as I have been accustomed to term it, tetanilla, is to be found. Neurasthenia, either attacking the sound organism or one which is already neurotic, is by no means rare in Europeans. It was quite common with its gastric phenomena in the male and female shoemakers in Lynn, Mass. Nearly forty years back there was a condition so closely resembling it there that it was first described as epidemic, and then as endemic. This so closely resembled tetanilla that it could be placed under the same category. It was then charged that a good many of the conditions were due to dyspepsia, and dyspepsia in those days meant a large number of neurotic states charged up to these gastric conditions. In dealing with these and allied conditions of the intestines the fact is often ignored that they are not primary, but secondary to a constitutional condition. Glénard, when he dealt with enteroptosis, did not take into account the fact that very frequently nerve tire and allied conditions preceded the neurasthenia to which he charged them. This would seem to serve as a predisposing factor. With regard to the direct etiologic factor I can see good reasons, from what is known of many of the morbid products (call them alkaloids, toxins, leukomains or allied products), why they should produce this condition. Certainly the occurrence of tetanilla in connection with infantile scurvy or rickets bears out Dr. Preble's position as an exciting factor of this kind.

Another thing which is purely hypothetical is whether interference or partial inhibition of the functions in gastrectasis may not produce the temporary, or, in some cases, permanent atrophic changes to which Dr. Preble has referred.

Dr. PREBLE (closing the discussion): It was not my intention to enter into the pathology of gastrectasis. The case, simply as one of gastrectasis would have no interest, and only little interest as one of gastrectasis with tetany or a tetanoid condition, but because we find here a tetanoid condition with drum stick fingers, both apparently due to a gastrectasis, the case seemed to me to be worthy of record. I must accentuate again the criticism manifested in regard to Dr. Turck's use of the words tetanus and tetany. One condition is absolutely distinct from the other and they should not be confused. The last case mentioned by Dr. Turck would seem to be one of tetanus rather than tetany, and if so, it has no place in the consideration of this subject.

In regard to his first case there are one or two things which attract my attention. In the first place I have never seen opisthotonic convulsions with tetany, nor have I ever heard of them occurring with it. There is, however, a functional neurosis often accompanied by opisthotonic convulsions, namely, hysteria, and with hysteria we frequently have epileptoid convulsions. It might, however, be that she had tetany, and associated with it epileptoid convulsions. The line between the two can not be so nicely drawn as to say that she had tetany and later on an epileptoid condition. It is more interesting to note that in these cases the masseters are more frequently involved than in ordinary cases. Tetany as it occurs in normal individuals, especially in shoemakers, is rarely accompanied by spasm of the masseters. The external muscles of the eye may also be involved in the spasm, but not

as often as the laryngeal muscles, particularly the laryngeal muscles in rachitic children.

Dr. Kiernan spoke of a condition which resembles tetany as being observed in the factories of Lynn. I am much interested to hear of these cases, for tetany seems to be rare in this country. I saw a number of cases abroad, so that its clinical picture is familiar to me, but I have not seen one here. This case is not typically tetany at all. The most we can say is that we have tetanoid conditions. So far as I have seen (and my opportunities for observation have not been ideal by any means) the case lacks two important signs, namely, spasm following pressure over the large vessels or nerves, and facial phenomena. These are absent entirely.

In regard to the use of the word *tetanilla*, I never heard it employed until Dr. Kiernan used it, and then I was interested enough to look it up. I found the word *tetanilla* was proposed by Trousseau many years ago, but in his lectures he makes no use of it. He makes use of the word *tetany* only. One has to hunt the dictionary or monographs upon tetany to find the word *tetanilla* at all.

AMPUTATIONS AT THE KNEE JOINT.

Dr. WM. CUTHBERTSON—This is an operation of considerable antiquity, having been advised by Hoin in the last century and reintroduced by Brinton, Velpeau, Markoe and others.

In discussing amputations at the knee, various causes requiring the operation must be taken into consideration before determining the operation to be performed. It is a foregone conclusion that in all crushing injuries, such as railroad accidents, limbs being caught in machinery, wounds of the femoral or popliteal arteries, the incision must be made according to the extent of the destruction of tissue or the location of the arterial wound. Again the amount of shock resulting from the injury must be considered as a determining factor, it being a well known fact that the higher the point of amputation the greater the shock and consequent mortality. The third determining factor is the ability of the patient to procure a prosthetic appliance to replace the loss of the amputated limb.

It should be imperative that the line of suture in all cases of amputation at the knee joint should be behind and not across the end of the stump.

MORTALITY OF KNEE AMPUTATION.

An analysis of a mortality table compiled by John Ashhurst, Jr., M.D., in the International Encyclopedia of Surgery, Vol. 1, 1888, gives a death rate of 50 per cent. A later compilation by the same author in 1895 of seventeen cases with eight recoveries and nine deaths gives a mortality of 52.9 per cent., or a total mortality in both series of 52.4 per cent. These cases comprise operations for all causes.

A further analysis of these statistics shows that of seven amputations by the antero posterior flap method through the knee joint, four died and three recovered, a mortality of 57.1-7 per cent. Amputation by the same flap method through the condyles of the femur, nine operations were performed with five deaths and four recoveries, a mortality of 55.5-9 per cent.

From statistics of the Civil War 132 cases are reported with 64 deaths; mortality 48.4 per cent. Of these, 49 were primary with 16 deaths, a mortality of 32.6 per cent. Brinton gives 62 cases for disease with 14 deaths, a mortality of 22.6 per cent. Max Schede gives in civil practice for injury 314 cases with 103 deaths, a mortality of 32.8 per cent. For disease 124 cases with 30 deaths; mortality 24.4 per cent.

Riobanc (year book 1897, page 229) gives the records of 85 cases of Gritti's operation with a mortality of 19 per cent.

He states not one of the deaths was due to the operation but to other causes. A further report of this operation gives 25 cases for injury with 4 deaths, a mortality of 16 per cent.; for disease 196 cases with 5 deaths, mortality 26.3 per cent.

Amputations through the condyles of the femur: For injury 111 cases with 40 deaths; mortality 36.1 per cent.; for disease 60 cases with 15 deaths; mortality 25 per cent.

Totals: Simple disarticulation, 648 cases with 220 deaths; mortality 3.3 per cent. Gritti's operation, 306 with 13 deaths; 4.2 per cent.

Amputation through condyles of femur, 171 cases with 55 deaths; mortality 3.2 per cent. Grand total, 1,125 cases with 228 deaths; mortality 2.50 per cent.

The age of the patient has a distinct bearing on the mortality of the operation; other things being equal, children stand amputation better than adults, the reason being, in my opinion, in addition to a better constitution, as a rule, the shock is lessened by the child not being aware of the enormous loss it sustains through the amputation of the limb. The operations which would seem to meet with the most favor are the following:

1. The antero-posterior flap method, formed by cutting an

anterior flap, beginning the incision near the back of the tuberosity of the tibia, curving around the front of the knee from one to three inches below the tubercle of the tibia and ending at a point half an inch below the head of the fibula. The ligamentum patellæ is reached, divided, the knee flexed and the lateral and crucial ligaments cut through; the knife is slipped behind the joint, an outward cut made and a short posterior flap formed. The edges of the flap are united, which brings the line of cicatrix well behind the condyles of the femur. In this operation the patella is preserved and, in my opinion, the articular cartilages of the femur should also be retained.

2. The bilateral flap method of Stephen Smith: An incision is made beginning below the tubercle of the tibia, curving downward and forward around the outer side of the leg, inward and backward to middle of leg, then upward to the popliteal space. Another incision, a counterpart of this, is made on the opposite side of the leg, the joint opened and disarticulated and the edges of the wound united by interrupted silkworm gut sutures.

3. Cardens' operation, in which a large anterior cutaneous flap is made. The deeper structures are divided down to the bone above the patella, the posterior incision is made, transversely from without inward on a level with the base of the anterior flap; the lateral and crucial ligaments are cut, the limb divided and the edges of the skin flap sutured.

4. is Stokes' modification of Gritti's operation. A long anterior and short posterior flap is made, the bone sawed through above the condyles, the posterior surface of the patella denuded with a small saw, the freshened surfaces of the patella and femur brought into apposition and sutured by catgut passing through the muscles of the thigh and the margin of the patellar structures.

A great objection to this operation is the sliding of the patella on the end of the femur and its annoyance to the patient as well as the danger of non-union occurring between femur and patella. I have obviated this by peeling back the periosteum from the lower end of the femur and, after approximating the femur and patella, sewing the periosteum to the margin of the patella. This makes a clubbed end to the femur and strengthens its attachment to the patella. Drainage should be used in all amputations at the knee. That operation which retains the patella is the preferable one. I am also of the opinion that all injuries which necessitate immediate amputation should be operated by the antero-posterior flap method with simple disarticulation, as this is the most easily performed. In operations of election, Stephen Smith's lateral flap or Stokes' modification of Gritti's should be selected: the latter, in my judgment, being preferable in robust persons, as it requires so much more time to perform, the lateral flap method being restricted to weakened constitutions.

The operation of simple disarticulation with preservation of the patella affords an excellent stump for bearing weight and in indiscriminate cases is the preferable operation. Gritti's operation leaves a bad stump, as the edges of the wound almost invariably become painful through pressing upon the socket of the artificial limb. Stokes' modification of this operation with the femur sawed through about two inches above the condyle, is a much preferable operation.

In all of these operations the skin should not be allowed to become adherent to the bone, as it is certain to cause pain and discomfort by being dragged upon by the artificial limb. Hence the advisability of preserving the patella.

The tendency of the patella to retract on the front of the thigh can be obviated by severing the quadriceps tendon above the patella.

(To be continued.)

French Association of Urology.

This association held its second annual general assembly at Paris in October, with Prof. Guyon in the chair, and a large attendance, including many foreign corresponding members of the association. In the address on "Hypertrophy of the Prostate," Carlier remarked that the five hundred cases on record in which castration has been performed, show a remarkable variety in the results obtained, some extremely successful and others entire failures. The consecutive mortality is quite large, 19 per cent., probably due to the previous physical condition of the patients. The operation has succeeded in cases in which there seemed scarcely any hope and has failed in others in which it seemed urgently indicated. It is difficult to explain the retrogression of the lesions if we accept Launois' theory that they are due to arterio-sclerosis, but if we adopt Albarán's suggestion that the hypertrophy of the prostate is a hypertrophic cirrhosis of glandular origin, we can understand

better the atrophy of the enlarged prostate after castration. Motz has found that 63 per cent. owe their hypertrophy to the abundance of glandular tissue. Arterio-sclerosis was not observed in the cases in which the glandular tissue was extremely abundant, nor even in those in which the glandular tissue formed one-half of the section. But the clinic is not able yet to differentiate between the hypertrophy due to glandular tissue and that due to the connective or muscular tissue, or sclerosis. Castration has accomplished many remarkable cures, and often induces a rapid decongestion of the prostatic apparatus, but its uncertainty, with its other disadvantages, forbid it a brilliant future. Resection of the vas deferentia is still more unreliable, and he thinks it probable that well-managed catheterization would have reduced the congestion of the prostate, as well as the vasectomy, in the successful cases. The future of this operation is therefore no more promising than that of double castration. Albarran described a new operation, which he calls "Angioneurectomy of the Cord." It consists in resecting for a short distance all the elements of the cord, with the exception of the vas deferens, the artery of the vas, and one or two of the accompanying veins. He has performed it on numbers of dogs and in three months the testes were completely atrophied. The prostate at the same time showed generalized atrophic lesions similar to those secured with double castration. This operation has been performed on a patient, but too recently to announce the results. Legue observed that if vesical contractility is entirely gone, intervention is useless. It only promises success when the lesions are recent and probably not severe. In incomplete retention with diminished but not suppressed vesical contractility, he has obtained excellent results with both castration and vasectomy. Desnos reports the observation of 296 elderly patients with urinary troubles. In 220 the prostate was enlarged. Among these there was retention in 112 and 108 without. Under the age of 65 there was retention in 14 to 80 without. Above this age the proportion was reversed, 98 with retention to 28 without. Examination of 76 patients with retention, but without enlargement of the prostate, showed the same relative proportion in regard to the age. The conclusion seems to be that the prostatic hypertrophy is not a factor in the retention of urine, a conclusion evidently exaggerated, but still not without significance. The recent results reported show for castration seven brilliant successes (Legueu, Chevalier, Loumeau and Motz); two complete failures; three much improved. Loumeau noticed a decrepitude and weakness in his two cases afterward greater than the age warranted. His 21 vasectomies did not affect the functions nor the condition of the prostate in any case. Carlier reported 9 satisfactory vasectomies. Motz 3 vasectomies; 1 case cured; 1 not benefited, and 1 died in seventeen days. Nicolich 27 vasectomies; 8 completely cured; 3 still continue to have sexual relations; 14 improved; 5 unaffected. One vasectomy was reported in which the patient was relieved of some calculi at the same time, and possibly the marked benefit derived may have been due to this fact. No new cases of psychic disturbances from either castration or vasectomy were noted in the reports presented.

Carlier reported a case of tumor in the left kidney the size of a man's head with periodic attacks of hematuria but no other disturbances. The general health is perfect, although the patient has been carrying the tumor for ten years. He queries whether the result would have been any better after nephrectomy than at present. Chevalier described a case in which one kidney had been removed for uropyonephrosis, followed later by a similar condition in the remaining kidney with total anuria and grave symptoms. Lumbar nephrotomy released an enormous quantity of urine and the patient recovered at once, although the fistula persists to this day and all the urine is discharged through it; Chevalier considers it the safeguard of her health, as renewed tension of the kidney would certainly terminate fatally and advises keeping the fistula open the rest of her life. Bégouin stated that absolute anuria from calculi lasting forty-eight hours should be treated like a strangulated hernia. If medical treatment (morphin, electricity and massage of the urethra, elastic compression of the inferior members, etc.) energetically applied, is not followed by success in a few hours, an operation should be performed without delay. Legueu and Donnadien consider five days the longest limit of delay. Numerous incidents were related in which intervention at the fifth to seventh day were followed by death. Although the operation had succeeded in restoring the functions, it had been too late to save the patient from uremic intoxication. "The importance of varicocele in the diagnosis and prognosis of renal tumor" was confirmed by Legueu, who has established that the compression of the spermatic vein is not produced by the tumor, but by degener-

ated ganglia. The varicocele is only the external manifestation of the secondary adenopathy, and bears no proportion to the size of the tumor. If a cancer therefore is accompanied by a varicocele, the conclusion should be that there is already ganglionic propagation. This conclusion attenuates the hopes based on the small size of the tumor, and if operated, the ganglionic masses should be removed with it. Eraud's address on "Non-gonococcal Urethritis" emphasized the prevailing tendency to consider that specificity comes less from the species, whose rôle is rapidly dwindling in importance, and more from the poison, which is constantly acquiring greater significance. He concluded with the statement that the problem is more complex than hitherto supposed. Along with the polymorphism of the microbes there is the question of the toxalbumins, scarcely outlined as yet, which may locate farther still the mechanism that we have been ascribing to the single rôle of the microbe; in other words, behind the microbe hides the poison. Hogge urged that greater attention be paid the prostate in cases of primary urethral suppuration, as its anatomic conditions render it especially liable to react to inflammation. Carlier and Daret observed that the vesical phenomena accompanying renal tumors and tuberculosis must not be considered a counter-indication to surgical intervention otherwise called for, as they frequently are but a reflection of the renal trouble and subside with it. J. Albarran confirmed the success of his cystoscopic catheterism of the ureters already announced, and Sorel described a form of neurasthenia in which acute retention occurs periodically, cured by catheterism. Boursier suggested that a bath will sometimes cure these cases if catheterism is difficult.

PRACTICAL NOTES.

Pruritus an Early Symptom of General Paralysis.—Sarbo has observed two cases in which an intolerable pruritus was the first symptom of the disease.—*Semaine Méd.*, from *Pesth. med. chir. Presse.*, Sept. 12, 1896.

Parenchymatous Injections of Alcohol in Actinomycosis have been found a valuable adjuvant of the potassium iodid or surgical treatment. If they do not cure directly they render the foci more amenable to other treatment, especially surgical intervention.

Thyroid Chlorosis.—Capitan believes that certain forms of chlorosis are traceable to disturbances in the thyroid gland, and has found marked improvement follow iodine treatment, and also that the patients were almost entirely cured in four to five weeks on administration of iodothyron tablets.—*Semaine Méd.*, December 22.

Buckskin Dressing for Eczema.—Davesac has found that buckskin applied over the salve, fits smoothly to the surface, yielding to every movement, never rots nor produces erythema, does not absorb the salve and does not stick to the tissues, while it is easily washed and keeps the dressing moist inside and dry without, and the scabs leave a healthy surface when they drop off.—*Semaine Méd.*, December 22.

Radiography of the Skull.—Contremoulins' apparatus locates a foreign body in the skull with absolutely mathematical accuracy, but its expense forbids its general use, although it is highly endorsed by several members of the Paris Acad. de Méd. Approximate accuracy is secured by Mergier with a very simple and inexpensive apparatus, which has rendered invaluable service in the hands of Pean and others. He first quarters the field with two straight wires at right angles, which alone is a great help in locating the foreign body.—*Bulletin de l'Acad. de Méd.*

Liebmann's Method of Treating Stuttering.—A hundred severe cases cured in the brief space of four weeks are reported by A. Liebmann of Berlin (*Memorabilien*, November 13). He has the patient repeat sentences after him, drawing the vowels and pronouncing the consonants sharp but distinctly, maintaining the conversational tone throughout without any rhythm, and avoiding the singing tone altogether. When the patient finds himself thus speaking several sentences fluently at the first sitting the psychic stimulus is immense. The method can be applied to quite small children.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JANUARY 22, 1898.

THE MEDICAL CARE OF THE SEAFARING CLASS.

The U. S. Marine-Hospital Service has in late years come into such notoriety in connection with the proposed establishment of a National Department of Health that its proper office has quite dropped out of sight. A considerable number of educated people, even among the medical fraternity, believe it to be an institution for the care of sick *marines*, and many others, who are cognizant of the Marine Corps as a part of the United States Navy, identify it with the medical department of the naval service, and infer that this association with National vessels and through them with foreign countries where naval officers are brought in contact with the breeding-places of the great maritime pestilences, justifies the assignment to it of the duties of a seaboard quarantine. This confusion of function has been one of the obstacles in the way of the establishment of an organized independent National Health Department. The officers of the Marine-Hospital Service know nothing practically of these alien pestilential breeding-places; they have no reason to know it. Their duties properly restrict them to the treatment and care of the sick and disabled seamen among the crews of merchant vessels, at the commercial ports on the sea-board and lake-board. The U. S. Marine-Hospital Service was created for this purpose and for this solely. Its hospitals have been built and dispensaries and sick-quarters established for the benefit of the crews of merchantmen only, as U. S. Naval Hospitals receive only the officers and crews of men-of-war and other National vessels, the sailors and marines (sea soldiers) of the U. S. Navy. For this medical care of the mer-

cantile class, Congress has appropriated liberally and the numerous Marine Hospitals have been erected well equipped with every modern appointment and officered by a corps of carefully selected, thoroughly competent physicians and surgeons of deservedly high repute in the profession. In the organic law, instituting the Marine Hospital-Service, this was all it was expected to do. The relegation to it of quarantine duties, a part only of the responsibilities of a National Health Department, has come about without predetermination, and now that the wisdom of such an assignment is contested, the claim is made that the material for such a department exists within the Marine-Hospital Service, which can be developed without much further expense to the Government. An establishment already equipped as this is, it is said, can do all the work required without change of personnel, additional expenditure, or interference with the other duties of the officers to be diverted to it.

Can this be so? Is it possible that the officers of this strictly hospital corps can be detached from their original and legitimate duties to assume this charge without the appointment of others to take their places? Why should the physician employed to take care of the sick of the vessels of the merchant service be sent to foreign countries and located at foreign seaports and consulates? With better reason, medical officers of the U. S. Navy might be detailed for this duty. Is there any other reason for the hybrid sought to be consummated than the accidental one that the officers of the Marine-Hospital Service are employes of the Treasury Department, which Department has control of the commerce of which these merchant vessels are the carriers. There is very evident disposition at Washington for each department to extend its operations in every possible direction and any attempt at abridging this amplification is resented. As sick sailors were taken in charge by the Marine-Hospital Service and cared for in the Marine Hospitals in cases of ordinary ailments when they were affected with communicable diseases of the pestilential class, it was taken for granted that this Service was the proper one to consider the means for the prevention of their communication; and as this evidently was a matter of National cognizance, involving, as it did, foreign relations, the need was admitted for some uniformity in the provisions for the inhibition of these maladies as menaces of the public health; and as other diseases were no less prejudicial to the general health, the necessity for their restriction and control was recognized and it was evident that the department which had the power to hinder the spread of foreign-born communicable diseases should also have control of these, and hence the assumption that the Marine-Hospital Service was that specially endowed department. Thus, step by step this Service has strayed farther and farther from its proper field, and the time

has come when the medical profession shall consider whether the National sanitary interests do not demand something else for their administration than the makeshift adaptation of a bureau specially constituted for other purposes.

But quarantine is only a small part of the matter; there are great and important functions for the new department quite outside of quarantine and irrespective of it which can not be performed satisfactorily by the Marine-Hospital Bureau.

Happily the State boards of health are examples of such an organized establishment for the Nation as they are for the States, a National Department of Health harmonizing, unifying, connecting and supplementing all these in accordance with the representative character of our American institutions. The Department of Health as at present proposed simply creates an independent bureau, such as the Department of Agriculture was before its chief officer became a cabinet officer, and such as the Department of Labor now is. An *ad caplandum* appeal for the sympathy of the medical profession has been made in the gratuitous assumption that the advocates of the bill before Congress, which has the *indorsement* of the AMERICAN MEDICAL ASSOCIATION, the American Public Health Association and the State boards of health, are urging the creation of a Department of Health with a politician instead of a physician as its chief. Were there but one physician in the United States eligible by reason of recognized ability as a sanitarian to be chief of such a department this might be feared, but as long as such men live as WALCOTT and ABBOTT of Massachusetts, STEPHEN SMITH and RAYMOND of New York, ROHÉ and WELCH of Baltimore, MATHEWS and MACCORMACK of Kentucky, HOLT, WILKINSON and OLLIPHANT of New Orleans, HORLBECK of Charleston, PORTER of Florida, and the multitude of able and experienced sanitarians of the Northwest, who drew their inspiration from the illustrious JOHN H. RAUCH of Illinois, all physicians, there is no reason to fear that an honest, intelligent, able and impartial President of the United States, such as is the present incumbent, will ever call to this high office a man who is not physician as well as politician, using the latter word in its honorable and legitimate sense of "one versed in the science of government." The Supervising Surgeon-General of the Marine-Hospital Service has abundant opportunity for the administration of his own bureau, and were he ten times as able he can find therein all that he can do, if he do that all well. *Ne sutor ultra crepidam.*

TO HELP THE CAUSE, let each member of the ASSOCIATION write his Senator and member of Congress at once in regard to this matter. If it is understood that the *whole* profession really take an interest in the matter the local lobbyists at Washington will be powerless to stop the reform.

THE SURGERY OF THE THYROID FROM A NEUROLOGIC STANDPOINT.

In a suggestively written paper in the January number of the *American Journal of the Medical Sciences*, Dr. J. J. PUTNAM uses the following words: "We are rather in the habit of assuming that the removal of large portions of the thyroid does no harm, provided it does not cause myxedema. But the probability is that we shall learn to recognize affections which lie between myxedema and health, as well as peculiarities of development and disorders of nutrition for which the thyroid is more or less responsible." . . . That this is a statement of fact will hardly be disputed by any neurologist, but that it expresses a truth that has as yet been insufficiently impressed on the profession generally is another fact the importance of which is not likely to be over-estimated. It is only within a comparatively brief period that we have learned that the thyroid had any definite function and our knowledge of its physiology is still very far from being exhaustive. The dangers also of interference with it are as yet also only partially known, but it is certain that they are not confined to the operation itself. The cases of sudden fatal dyspnea occurring hours after an apparently prosperous operation in Graves' disease, recently reported by DEBOVE and others, are in evidence of this, and Dr. PUTNAM adduces other important facts and arguments against any too venturesome surgery of the thyroid gland. Among these are the experiments of HALSTED showing that excision of the gland in dogs had a serious and very evident disturbing effect upon their offspring and that even very slight operative interference produced hypertrophic changes and apparent increase of secretion in the gland itself; and the observations of KOCHER of goiter and cretinism inherited from parents with no disease other than impaired thyroid function are also cases in point. Still another fact brought forward by PUTNAM is the one that removal or atrophy of the thyroid in infancy checks the growth and function of the reproductive organs, and gives rise to the various disturbances of development that follow the suppression of this very important function. The close relations of the various internally secreting glands, the thyroid, the testicles and ovaries, the suprarenal glands, and the pituitary body, for this it seems probable must be included in this category, are revealed in many pathologic conditions and the thyroid as the largest, and presumably the most important, has apparently a larger part in the disturbances than any of the others. It seems to be involved to some extent in many cases of acromegaly; its relations with the genital development have already been mentioned, and its implication in many pathologic conditions of organs is probable and is strongly suggested by the clinical history in certain cases of Graves' disease. SEELIGMANN has indeed recently reported a case of

this affection apparently closely associated with genital disorder in which he obtained decided benefit from the administration of ovarian extract, thus adding another suggestion to the therapeutics of the disorder.

When any organ is removed, as PUTNAM says, two factors are set in operation which may have more or less important effects upon the system generally. One of these is the action of toxins, the other is the effort of the organism to adapt itself to the new and changed conditions. The first of these is important enough in the case of removal of the thyroid gland, but the other, from what we are beginning to know of its physiology, must be even more important. Because the function of the organ is already deranged it does not necessarily follow that matters will be remedied by its removal. The operation may only make a bad matter worse. The mortality of thyroidectomy, according to PONCET, is from 15 to 30 per cent., which is alone enough to induce caution. When the facts brought forward by Dr. PUTNAM are also considered, the known and the possible and hinted though yet unknown effects of thyroid ablation, there is still more reason for prudence and hesitancy in this operation.

Of course when a goiter has become a dangerous mechanical embarrassment to important functions, or when a tumor exists in the thyroid that by its growth and situation has become a threatening danger, the case is clear and operation may not only be justifiable but necessary. It is in such affections as Graves' disease, in which thyroid operations are still somewhat popular, that we are likely to have not only useless but dangerous surgery, and the time seems to have come to emphasize the cautions implied in Dr. PUTNAM's paper. The theory of hyperthyroidization in this disease, though it has apparently much in its favor, is not yet sufficiently demonstrated, and even were it so would not form a justification for any indiscriminate or frequent practice of operative interference. Graves' disease is not by any means a hopeless disorder under medical treatment, even in its advanced stages: it is therefore impossible to say when surgery is indicated as a last resort. When the facts of its absolute inefficiency in perhaps the larger proportion of instances in which it has been tried, the immediate dangers of the operation which are not slight, and the remote ones pointed out by Dr. PUTNAM, are all taken into consideration, it would seem that it ought to be relegated to innocuous desuetude.

ON THE PRESENCE IN THE BLOOD OF FREE GRANULES DERIVED FROM THE LEUCOCYTES, AND THEIR POSSIBLE RELATIONS TO IMMUNITY.

H. F. MUELLER¹ of Vienna recently described certain small, round, colorless granules as constantly

present in the fresh blood. These granules were regarded as entirely distinct from the blood plates. This observation did not seem at first to attract very much attention. In the last number of the *Bulletin* of the Johns Hopkins Hospital WM. R. STOKES and ARTHUR WEGEFARTH publish an article from the Bacteriological Laboratory of the Health Department of Baltimore, in which they state that they have confirmed MUELLER's observation, and in which they recite a number of very interesting experiments that appear to throw considerable light upon the much discussed question of the relation of the leucocytes to the bactericidal properties of the blood serum and to immunity.

MUELLER described these bodies as small, round and colorless, about the size of the finest fat granules. They are highly refractile and show a dancing molecular movement, but have no independent motion. MUELLER concluded that these granules are normal constituents of the blood, but he does not consider them as oxyphile or neutrophile granules that have escaped from the leucocytes, and he leaves the question as to their fatty or albuminous nature open. STOKES and WEGEFARTH were able to demonstrate these granules in the fresh blood taken in dispensary clinics and otherwise from about 500 persons. Having observed that these granules occurred in all specimens of blood examined, the question naturally arose as to their origin. It was noticed that when examined by artificial light, as for instance by means of the Welsbach gas burner, the granules resembled very much those found in the protoplasm of the oxyphile and neutrophile leucocytes. When a blood specimen is surrounded by vaselin so as to prevent drying and then exposed to a temperature of 35 degrees C. for an hour or more, the granular leucocytes became actively ameboid, the granules in the neutrophile cells become very lively, and the number of granules in the blood plasma becomes perceptibly increased. The characteristic dancing motion of the granules of the neutrophile leucocytes is shown very well by simply mixing the drop of blood with an equal amount of distilled water containing 1 per cent. of alcohol. The investigators believe they have noted that these granules may leave the protoplasm of the ameboid leucocytes.

Under similar conditions the granules in the oxyphile (eosinophile) leucocytes also show a tremulous motion, though less vigorously.

The blood of various animals was also examined as regards the presence of these granules, and it was found that the observations made concerning the human blood are in the main applicable *mutatis mutandis* to the blood of horses, rabbits, cats, guinea pigs, rats, frogs, fishes, etc. These observations strengthen the conclusion that the granules of the oxyphile and neutrophile leucocytes may appear as free bodies in the blood serum.

¹ Centralb. f. allg. Path. u. path. Anat., viii, 1896.

After reviewing the two principles in regard to immunity, viz., METSCHNIKOFF's well known theory of phagocytosis, and the theory of those investigators that attribute immunity to the bactericidal properties of the blood serum and to the extracellular action of the leucocytes, STOKES and WEGEFARTH detail certain investigations for the purpose of determining whether there existed any difference in the bactericidal power of fresh blood serum before and after it had been filtered through new sterile Möncke filter cylinders. From these experiments it appears to be demonstrated that the filtration of the serum of the guinea pig and rabbit through new porcelain filters removes its normal power of causing the agglutination and cessation of motility of many motile pathogenic bacteria and of destroying large numbers of these organisms. This power can be restored by adding to the serum leucocytes, free granules and red blood corpuscles. As the red blood corpuscles are not regarded as bactericidal it follows that the restoration of the bactericidal power is due to the leucocytes and free granules, and that these cells can furnish bactericidal material.

Having demonstrated that the leucocytes not only contain bactericidal substances, but also under certain conditions can give up the power of their protoplasm to the surrounding medium, it naturally became tempting to try to show by means of some experimental proof that the germicidal substance and the granules that leave the leucocytes are related or identical. This proof is, however, extremely difficult to furnish. STOKES and WEGEFARTH added the typhoid bacillus to various normal bloods and serums, but did not notice any distinct attraction of the bacillus for the free granules. Having immunized guinea pigs against the typhoid bacillus and adding a 24 hour culture of motile bacilli to the fresh blood of such animals it was found that the bacilli became motionless and clumped, and that in about fifteen minutes fine granules could be seen around the periphery of the clumps and in the meshes of the massed organisms. Often several granules could be seen about a certain bacillus. It will be recalled that VAUGHAN and NOVY² extracted a germicidal nuclein from the serum, which they think is derived from the leucocytes, and that HANKIN³ believes that the granules of the eosinophiles gradually become dissolved in the serum and thereby furnish the protective substance or alexin found in the blood serum. The work of KANTHACK and HARDY⁴ is also very suggestive in connection with this phase of the subject.

Upon injecting anthrax bacilli into the various lymph sacs of frogs they found that the destruction of bacteria could be divided into two distinct stages: In the first oxyphilic leucocytes approach the chains of

bacilli. These cells then apply themselves to the surface of the bacilli and discharge their granules by quick, streaming motions, when the bacilli begin to show signs of degeneration. Then follows phagocytosis of the degenerating bacilli by the hyaline cells. STOKES and WEGEFARTH repeated these experiments and found that any distinct clinging of the oxyphiles to the anthrax bacilli did not occur, but that the cells very soon appeared to contain much smaller numbers of granules than before, and that many large (oxyphiles) granules could be found free in plasma, as well as small, dust-like granules which they believe are derived from the polymorphonuclear (finely granular) leucocytes. They conclude, therefore, that it seems likely that the free granules both from the oxyphile and the finely granular or neutrophile leucocytes may weaken and destroy anthrax bacilli by their presence in the plasma, and that the work of destruction is completed by phagocytosis.

The many suggestive facts which have been hinted at imperfectly induce our authors to advance the following theory: First, the bactericidal power of the leucocytes of the blood and the serum of man and many animals is due to the presence of specific granules, derived especially from the neutrophile and oxyphile granular cells. Second, in order to resist the action of invading bacteria the granular leucocytes can give off their granules to the surrounding tissues. Third, this throws light on the bactericidal powers of cell-free fluids, and this mode of production of alexins also offers an explanation of the hyperleucocytosis of infection. At the same time the supposition or observation is not disproved that leucocytes can act as phagocytes and take up bacteria either while alive or after they have been destroyed by the germicidal granules. It seems to us that these investigations are of especial interest, because they appear to throw additional light upon the protective and adaptive processes that occur in the reaction of the organism to local and general infection, and because they in a measure reconcile the two theories that obtain in regard to the mode that these protective mechanisms perform their functions, namely, that of intracellular action or phagocytosis and that of extracellular action due to the microbe-killing powers of the serum. The investigations also open up an apparently fertile field for further studies in regard to these important phenomena as they occur in the various forms of infection and intoxication.

MEDICAL LIBRARIES.

In going over a list of the principal public medical libraries of the country one is struck with their peculiar distribution. We notice one in Maine, another in South Carolina, a third in Colorado, while between lie many more populous States, some of them known as centers of medical education, without any public medical library at all.

² Promatnes and Leucomatnes, 1896.
Centralt. f. Bakt., xii.

⁴ Phil. Transactions, clxxxv, 1894.

Considering more closely the towns in which some of them are located the facts are yet more striking. For instance, in Maine the library is situated in Brunswick, a town of 6,000 inhabitants, the twelfth in point of size in that State. It belongs to the Medical School of Maine, Bowdoin College, and by the figures before us is larger than any other medical library in New England, outside of Boston. Again we find the Medico-Chirurgical Faculty of Maryland has a very respectable library, while scarcely one of the larger State Medical Societies has anything of the sort worth mentioning.

Medical libraries have not developed in response to certain peculiarly favorable conditions confined to large cities. It seems clear that most of them have been built up by the activity of a very few individuals, sometimes aided by a local institution or society, sometimes without any aid whatever. They are in many instances enduring monuments of the work of a single member of our profession, who perhaps was, apart from this, the busiest, most overworked man in his community.

These facts should be brought prominently forward because of the encouragement they give to others to take up this line of work. It seems that in almost any town in the country the conditions render possible the formation of a good medical library and wherever one is formed it will be a lasting public benefit.

The subject is one of real professional interest, and we are glad to learn that Dr. C. D. SPIVAK of Denver is collecting facts for a more complete account of the medical libraries of the country than now exists, to be brought before the coming Meeting of the ASSOCIATION in that city, and in due time to be laid before our readers. It is to be hoped that those who have given thought and labor to the subject will use this opportunity to place many valuable suggestions before the profession.

Dr. SPIVAK has himself suggested an important idea and has carried it into practical effect in connection with the Colorado Medical Library Association of Denver. He prepared a card catalogue of the medical works to be found in the private libraries of that city, which were not represented in the public medical library. In this way he was able to add more than 6,000 volumes to the medical works generally available for reference to the profession of Denver.

Some such plan might be followed in any large town or city and would be of very wide benefit to the profession. The essence of a reference library is to have the books obtainable, with some ready means of knowing just where each is to be found. It is not necessary that they should all be collected under one roof and one ownership. It is only necessary that their titles and location should be furnished in a well-arranged catalogue.

Probably in every city in the country may be found

several private collections of medical books. Even where large public libraries exist they lack many valuable books of reference that might be found on the shelves of private libraries in the same city. A card catalogue representing all of these books, and giving their location and the hours at which they might be consulted, would furnish each of these cities with a good practical reference library, or greatly extend the value of the library it already possesses.

The work of preparing such catalogues should be done by the younger members of the profession; they can furnish the time and energy, their older colleagues can furnish the books. Only bring the two together and a great professional benefit will result to both. The physician with a large private library finds with each addition to it an increasing difficulty in remembering just what he has to refer to and comes to feel keenly the need of a good catalogue; which he can not supply for himself, and can not secure without the aid of some one with a medical education. The catalogue of his own books would be worth far more than the inconvenience of having them consulted by others would ever cost; and to have with it also the access to all medical works in his city that he does not possess would be a practical extension of his library that he could not hope to accomplish in any other way.

On the other hand, for the young man who will take up this work of cataloguing, the opportunity is one of unmixed benefit. In arranging and classifying the medical books in the catalogue, he will be arranging and classifying the facts of medicine in his own mind; and at the same time learning just where he can put his hand on any particular reference when he wants it; and acquiring for all practical purposes (when he most needs it), a library such as he could never hope to buy for himself, no matter how great his professional success in after life.

With the private medical libraries of a city thus connected by a catalogue it would be almost certain that with the death of an individual owner his collection of books would not be allowed to become scattered or sold as waste paper. But the necessary effort would be made to secure them for permanent usefulness, in the possession of some medical society, or general public library, or educational institution, there to develop by accretions of similar sort into a true public medical library.

Will there not, before the time of the Denver Meeting, be other cities to report experience with Dr. SPIVAK's plan?

CORRESPONDENCE.

The Lepa Conference Again.

NEW YORK, Dec. 15, 1897.

To the Editor:—Dr. Dyer, one of the editors of the *New Orleans Medical and Surgical Journal*, has published on his

return from Berlin, where he attended the Leprosy Conference, not only a very accurate (I have the Berlin *Wochenschrift* before me) report of the doings of the Conference, but also a very curious one. It has a quality, which I'll be bound, will not be encountered in any reports of the same events, now being published or hereafter to be given to the world by his European colleagues; it will be found even, or rather especially, outside of the profession intensely amusing. Would those Teutons, Latins, Scandinavians, Slavonians, have ever imagined that the novelty of their European festival, the great men assembled in the capital of Germany, the beer and the emperor could violently *wake to ecstasy the living lyre* of a Yankee (as they call all Americans)? This ebullition of Pindaric lyricism (for has not the author come back, as it were, from the Olympian games; not, indeed, with palms and bays, but with that precious badge?) is not, however, the only condiment (excuse mixed metaphors) with which Dr. Dyer has tried to give flavor to his tale. Something of a more pungent nature seems to have been required by his literary taste, *das Streng mit dem Zartem*; it would be ridiculous to doubt that Dr. Dyer understands so much German. He thus conceived the happy idea of having a Turk's head, at which he might pound away for the delectation of his audience, and perhaps, who knows? to make good some harmless boast uttered in the blissful trance of those never to be forgotten days—that he would settle the hash of his Yankee colleague (give him time to return!) and let him have it right down the neck. Dr. Dyer, in fact, has gone out of his way to throw out at me a handful or two of vague and rather obscure obloquy. Does Dr. Dyer really think himself such a deep-rooted authority because, forsooth, he belongs to what he ludicrously calls the *personnel* of the Berlin Conference, that he may safely dispense with knowing himself what he means when he girds at his neighbor? "The relation," says the New Orleans member of the Berlin *personnel*, "of Ashmead to the Berlin Conference was well shown when a resolution of his relating to a conference in 1898 was quietly dropped without discussion. Ashmead wrote in the *Sei-I-Kwai*, in far-off Japan, a vituperative article which reflected upon the intelligence, upon the purpose and upon the ability of the *personnel* of the Conference in Berlin."

First, then, Dr. Dyer avers that Dr. Ashmead wishing to proclaim his contempt of certain European personages (who ought to have been sacred to him, as they are to Dr. Dyer), of their *intelligence*, their *ability* and their immediate *purpose*, conceived the extraordinary idea of going to *far-off Japan* and there (probably at the foot of the renowned Fujiyama) blazed away and relieved his bile by unlimited vituperation. The imputation of such nonsensical conduct I consider as downright elander. If there is anything that I feel obliged to say (even if it should be vituperation) I am not in the habit, as my friends and even the others will testify, to run to the "Flowery Kingdom" or to the antipodes. The fact is, that the article in question was published February, 1897, in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, and that reprints of it were sent to all known (to me) European leprologists. The *Sei-I Kwai Medical Journal* of Tokio reprinted it July, 1897. Dr. Dyer, in a passage which I shall quote presently, speaks in a very indefinite and puzzling manner of *Ashmead and his methods*. Is this mention of my article, as published in *far-off Japan*, an instance by which we may judge *Dr. Dyer and his methods*?

As to the quiet dropping of Dr. Ashmead's resolution relating to a Conference in 1898, it does not by any means, whatever Dr. Dyer says show *Ashmead's relation to the Berlin Conference*. This rash assertion is simply the result of careless ignorance. All those with whom Dr. Ashmead has been in correspondence with for the last two years in relation to the Leprosy Congress know better. The relation of Dr. Ashmead to the Conference is shown by the presence in it of twenty-two persons who

represented their governments respectively. I do not wish to explain again here Dr. Goldschmidt's and my own idea of an international committee, formed by delegates of the different nations interested in the question of leprosy. I have, single-handed, fought for that idea and in a large correspondence discussed it with men of all parts of the world. Both Hansen and Ehlers were against it, and I say nothing that I can not prove. It did not obtain a complete triumph, I am sorry to say, but that it was, at least in a certain measure, successful no one can seriously deny. In this, modest as the victory may seem, appears *the relation of Dr. Ashmead to the Conference*.

"Ashmead conceived the Conference, and because men of world-wide honesty and reputation were making it a success, he tried to discourage interest in it by writing abuses of these men. In justice to Goldschmidt, to Hansen, to Arning, to Lassar and to Ehlers, who suffered most, the above should be said. Goldschmidt allowed himself to be led into the organization of a conference because of the objects aimed at and washed his hands of Ashmead and his methods as soon as he saw behind the veil.

"This was the end of the eventful Leprosy Conference, one which Ashmead ridiculed because he was not ring-master and manager as well as director, etc."

When Dr. Dyer states that Dr. Ashmead, after conceiving the Conference tried to discourage interest in it he does not seem to understand what an incredible mental phenomenon he is describing; this statement, which seems to Dr. Dyer quite natural and needing no further explanation, hardly requires to be seriously refuted: for am I not writing these lines in my office and not in a lunatic asylum? However, some persons who have been either disgusted or offended or abused by me are quoted. The reader of the *New Orleans Medical and Surgical Journal* is informed that shocked by the wickedness of my ways, Dr. Goldschmidt at last determined to *wash his hands of me*. It is clear that he was for a long time in utter ignorance of my nefarious proceedings, for he has written to me and encouraged me for the best part of the last two years, complaining of some persons considerably more than I did myself. However, it occurred to him to *look behind the veil*, and then he did not hesitate one moment to perform those condemnatory ablutions. But what did he see behind that metaphoric obstacle to sight? Evidently nothing but the constant, laborious, undismayed activity with which Dr. Ashmead was and still is trying to call the attention of the public to the possibility of stamping out by international arrangements a disease, of which as Dr. Dyer says, 2,000,000 of men are the victims, and which threatens the other millions. But why should I be accused of veiling what I was unremittently proclaiming with all my might? O, Lord, clear our style of metaphors!

But there are others, and I ask myself with sincere searching whether I ever blasphemed (it could not be called with a milder name) against Hansen. When I most displeased this eminent leprologist was, to the best of knowledge, when I intimated that the microscopic creature on whose discovery his great fame rests, has distinguished itself by gigantic ingratitude, inasmuch as it has never done anything in return for all the regard, study, observation, cultivation, etc., which have been lavished on it. That is hardly abuse. I also said that Hansen had been compelled, *notens volens*, to swallow the diluted delegational idea. That is the truth, and if it was not it would not be abuse, it would be a lie, or perchance, a mistake. And Arning? He and I are on the friendliest terms, which I am ready to show, if required. And Lassar. Let Dr. Dyer indicate one passage in any article or pamphlet of mine in which he was abused. I am not quite so sure, I admit, about Dr. Ehlers. I made, in speaking of him, a very few and, in my intention and opinion, very harmless jokes, for instance, about the 159 lepers he looked at in

Iceland. Was this joke or abuse? Dr. Dyer's article first conjured up that doubt in my mind. Ought not he to know? Is not he a judge? Who among his numerous readers will ever forget his delicate appreciation of Dr. Virchow's attic joke, when this venerable sage expresses his regret not to have been informed at an earlier period that free beer was to be had for the asking at the lunch counter!

There is, however, in these lunges of Dr. Dyer, made with what I take the liberty of calling a vicious but also ridiculous carelessness, one which claims a little more attention. It remains for me to explain to Dr. Dyer's readers, should they come across these lines, what must, if they take Dr. Dyer *au sérieux*, rather startle them. How could Dr. Ashmead, in New York, aspire to be the ring-master (whatever that may be) and manager as well as the director of the Berlin Leprosy Conference? And yet, this is easy to answer. Dr. Dyer means that Dr. Ashmead in every article he wrote for a long time insisted upon one point, from which he never swerved for one moment, that the Conference, or Congress as it was originally called, could only do one thing that was useful: obtain the enforcement everywhere of absolute isolation and the enactment of laws preventing the contamination of one country by another; that every thing else was vanity; that what would be said and read in the Conference and printed by the authority of the Conference, could be said, heard and printed everywhere without conference; that the time for talk should be freely admitted to be past, and that the mind of those who attended the first Leprosy Congress should rise to one great conception, easy to understand and easy to carry out and infinitely salutary to mankind. This is what Dr. Ashmead repeated indefatigably and, no doubt, he irritated some people.

There was once at Rome a senator who believed that the safety of his country depended on the destruction of a certain town in Africa. This man allowed no influential person to remain in ignorance of his views, and proclaimed them in and out of season after every one of his speeches in the senate: *Carthago delenda est*. Yet no one ever suggested that he intended to become the ring-master, manager and director of the republic. Dr. Dyer, happily, did not want to destroy Carthage, and could enjoy himself without getting at loggerheads with everybody.

"I was waked by the band Sunday morning and saw a host of soldiers going to the palace for new flags, and they marched merrily and looked well and they were men. Long live Berlin! Long live the Emperor! Long live the Leprosy Conference and its work!"

Suppose now I should indulge in some banter like that of which I rendered myself guilty against the renowned *privat docent* of Copenhagen, this dithyrambic gush, this touching imperialism (which might draw tears from a stone), and even the innocent enjoyment of the medal (reproduced in Dr. Dyer's paper) which informed those whom he met in Berlin that the bearer was a member of the Conference and that his name was Dyer, would suffice for a little string of light pleasantry. But it might be abuse. Perhaps even quoting Dr. Dyer might be construed into abuse of him. ALBERT S. ASHMEAD, M.D.

Appendicitis.

DETROIT, MICH., Jan. II, 1898.

To the Editor:—In the January 8 issue of the JOURNAL I found an article on appendicitis, by an old practitioner, opposing operation and advising conservative treatment.

The article refutes itself, as the report of eight cases with five recoveries and three deaths, or a mortality of 37.5 per cent., is so terrible that if surgeons would report any such mortality, a hue and cry would be raised which could be heard across the continent. I simply want to call attention to it for fear that the article might have been overlooked. It is the same

old story. By conservative treatment a good many cases will recover, and about 15 per cent will die. This man's statistics are far worse.

There may be surgeons who are ambitious and inexperienced and who consequently operate when a patient is convalescing and there is no need of it, but every experienced abdominal surgeon will refrain from operating when the patient is recovering, but will postpone it and urge an operation in the interval. However, all experienced surgeons urge *immediate* operation upon every case, claiming that if all cases are operated upon the mortality will not be more than 2 to 5 per cent. Although in that case a certain number will be operated upon who would never have another attack, still they can not be distinguished beforehand, and we claim best results by prompt operation in every case as soon as diagnosed. Of those five cases which recovered in the article spoken of, four will have recurrent attacks; some will die with the second, some will die with the third, or the fifth, or the tenth, but all will die from appendicitis, not to mention the long continued illness and the suffering they undergo in the meantime. So that out of eight cases there will finally be one who will live and have no recurrences, and all the rest will be dead. While if the eight cases had been promptly operated upon the first day, seven at least would have recovered and not been in danger of any subsequent attacks, and one might have died.

With this and the other side of the question, any reasonable and conscientious member of the AMERICAN MEDICAL ASSOCIATION can easily decide which is the correct method of treatment.

Yours truly, J. H. CARSTENS, M.D.

X-Ray Blindness.

NASHVILLE, TENN., Jan. 10, 1898.

To the Editor:—Though possibly it may already have been mentioned, I am not conversant with any report on what may be called X-ray blindness. During the Centennial Exposition here this summer there were several X-ray machines in operation. One of these was attended by a gentleman of my acquaintance, of more than average intelligence and observation, and also possessed of a fair amount of electric knowledge. He tells me that out of about 3,500 persons who looked into the tungstate of calcium screen, at his hand or other object, four were unable to see anything. They were not only unable to see the bones of the hand or other objects more or less opaque to those rays, but they could not even distinguish the fluorescent light; the interior of the box was just as dark to them as before the light of the tube was turned on. These individuals he allowed to make a number of trials, even bringing them back at night, so as to avoid the disturbance of daylight, but without avail; the screen remained persistently black. My acquaintance learned, also, that the general agent who installed the machines, possessed the same peculiarity. This gentleman said that though he had tried many times he had never been able to see anything in the screen. This condition, it seems to me, is one that would not be unexpected. The eyes of some individuals read, abnormally, certain colors, and that there should be some eyes unable to grasp the X-ray is no more remarkable than the phenomena of color blindness.

ERNEST B. SANGREE, M.D.

Another Interesting Case: An Impacted Quid.

CHICAGO, ILL., Jan. 15, 1898.

To the Editor:—The case reported by Dr. Tufts of Sioux Falls, in which death was caused by the sudden plugging of the bronchi with a quid of chewing tobacco, recalls a less tragic case in my own experience.

A number of years ago I had a paper hanger at work for me, who was using as a stage to reach the ceiling he was decorating, the top of a ten foot partition. Busy at his work with his head

thrown back as he looked directly above, he failed to notice that the board on which he was sitting was insecurely placed.

I had been watching the man, but had gone perhaps seventy-five feet away, when I heard a mighty crash, but no outcry. Calling out and receiving no reply, I hastened to the spot to find my man perfectly livid and completely unconscious. My first thought was that he had been killed, so free was he from all motion; no gasping and struggling, just an inert mass of flesh and blood.

The thought ran through my brain as I pulled his vest open to reach his heart, which, just as in Dr. Tuft's case, was beating, was that the distance the man had fallen had not been sufficient to produce such seemingly disastrous results. What was the trouble?

The man's mouth was open, and from it trickled a little tobacco stained saliva, hint enough to warrant my cramming my fingers down his throat and fishing out a great wad of moist fine cut that was simply packed in the back of the mouth, covering the trachea and extending down into it.

Hastily turning the man upon his face and giving him a few hearty thumps on the back, I had the satisfaction of seeing my patient within fifteen minutes cough himself back into lusty but somewhat profane existence.

The moral of my tale and that of Dr. Tufts is that the emergency physician should look out sharply for impacted quids.

JOHN E. BEEBE, M.D.

Bureau of Public Health.

UNITED STATES SENATE,
WASHINGTON, D. C., Dec. 23, 1897.

To the Editor:—Your favor of the 16th inst. has been received and read with interest. I note what you say with reference to the united effort on the part of the medical profession of our State, supported by the medical men throughout the country, in favor of the establishment of an independent bureau with a commissioner to be appointed by the President at its head.

There is no class of professional men in this or any other country more entitled to the highest consideration than that of the medical profession. Upon that profession the people always rely in times of physical distress in their everyday life, or in times when contagious diseases seize and threaten the lives of the people of a locality and the communities surrounding it, among whom the malady is likely to be spread.

I therefore should be very glad to be of service in any reasonable direction looking to the support and encouragement of the medical profession and also to the interest of the whole people. I think we have within a year or two had evidence that those in authority have failed in the performance of their whole duty in protecting the lives of the people against the ravages of yellow fever in certain portions of our country.

Wishing success in the conduct of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, I am, sincerely yours,

S. M. CULLOM.

National Legislation on Sanitation.

MILWAUKEE, Dec. 29, 1897.

To the Editor of the New York Medical Journal:—In an editorial in the last issue of your valuable *Journal* there appears the following statement: "The American Public Health Association bill seems to us a retrograde measure. It would involve a departure from all existing methods of departmental work. It would create, to stand between the executive of the department and the management of an epidemic, a deliberative body of forty-five men whose opinions would have to be had before action could be taken."

Permit me to state that this is not the meaning or intent of the measure at all. It is intended that rules and regulations can be made by the department concerning which every State

and Territory can have a voice, the only satisfactory way such rules and regulations can be adopted, and that such rules shall be standing provisions under which the head of the department can act at any moment when occasion occurs and without any delay whatever. No other bill thus far presented does more than provide for quarantine regulations, and such regulations are to be under the entire control of the Marine-Hospital Service. States are to have no voice in the matter, but must submit to the federal government. There are no provisions in any measure presented, except the bill presented by the AMERICAN MEDICAL ASSOCIATION and approved by the American Public Health Association at its last meeting, that provides in any way for internal sanitation, vital statistics, etc., so much needed, and which are far more important than the maritime quarantine provisions, which are but a small part of the needed sanitary legislation in this country. To say that the bill is retrograde seems to the writer to result from a very imperfect understanding of the measure. It is true that the bill as printed contains a number of errors and is more or less ambiguous in its language. A new draft of the bill is being made, and when it is introduced into Congress it will present a clearer meaning and we trust will be less objectionable.

U. O. B. WINGATE, M.D.

Medical Courtesy.

SHELBYVILLE, IND., Jan. 11, 1898.

To the Editor:—I can not agree with you in your answer to R. A. H. on "Medical Courtesy," in the JOURNAL of January 8. My understanding is, and has been for more than forty years, that on this point of medical etiquette the rule is the reverse of that in social life, and for very obvious reasons. When a physician locates in a town, it is his duty to call on members of the regular profession at the earliest convenient time, if he is a regular physician himself. By this action he manifests his intention to continue in the regular profession and wishes to associate with its members.

He may, as is sometimes the case, be changing his location for the purpose of engaging in quackery, and to avoid any embarrassments, he should be left free to indicate his future intentions, which he can do in an emphatic manner by calling only on those of the regular profession.

Very respectfully, W. G. McFADDEN, M.D.

BOSTON, Jan. 10, 1898.

To the Editor:—In the JOURNAL of January 8, page 104, "Medical Courtesy," I would suggest adding to the answer, but the newcomer should first leave or send his card as an introduction or announcement of his coming.

Respectfully, J. S. W.

Ans.—Amendment is accepted.

PUBLIC HEALTH.

Influenza at Angers.—The French exchanges mention that the hospitals at Angers are full and patients turned away, from an epidemic of influenza.

Hospital Contagion of Typhoid Fever.—A number of instances were related at the meeting of the Paris Soc. Méd. des Hôpitaux in which patients and nurses in the hospitals acquired typhoid fever, presumably from other patients. Stricter precautionary measures were urged upon the attendants and the use of special vessels, etc., for typhoid patients.—*Semaine Méd.*, December 22.

Health in Chicago.—The report for December, 1897, gives the total deaths during the month as 1,790, or 1.10 per 1,000 inhabitants, the rate for December, 1896, being 1.12 per 1,000. Of these 1,790 deaths 361 were persons under 1 year old and 204 from 1 to 5 years. The causes were: Diseases of the nervous

system 260, pneumonia 221, consumption 168, diseases of the heart 135, bronchitis 106, acute intestinal diseases 77, diphtheria and membranous croup 73, cancer 70, typhoid fever 35.

Large Special Grant for the Control of the White Plague in New York City.—The Department of Health of New York City, after petitioning the "City Fathers" for four years for financial support in its efforts to control the spread of consumption, has won a victory. The Board of Estimate and Apportionment has added to the health department budget for 1898 the sum of \$60,000 for the management of the tuberculous sick under the supervision of the department. In the argument for this allowance, or fund, it was alleged that one in seven of the deaths of the city was caused by tuberculosis, and that in some tenement districts the rate was one in four; that many hospitals would not receive such cases, and that the hospitals that received them sought to get rid of them as soon as possible. The Seton Hospital at Fordham Heights, which was built especially for consumptives, would receive patients at the rate of \$1 a day. Dr. Biggs, the health department bacteriologist and persistent warrior against the white plague, is reported to have stated that it was the purpose of the department to take charge of such patients as could not pay for treatment. He added that there was no longer any doubt that the disease could be stamped out if it could be properly treated and isolated.

Hygiene for Tourists in France.—Dr. G. Morice of Paris, has written a little book on the above subject. He points out the needs of travelers both on the train and at the hotel or auberge, emphasizing cleanliness as the great desideratum. But most important of all, the latrine accommodation should be above reproach. At present the filthiness of hotel privies in France is for the most part excessive. So much so, indeed, that in their *Revue* the Touring-Club have commenced what they call "La Croisade des W. C." "First nation in the world for touring, roads, and climate," says Dr. Morice in conclusion, "we are not yet within measurable distance of the English, the Americans, or even the Swiss, as regards ordinary comforts in our retiring closets. Then put your shoulders to the wheel, French landlords, and by paying a little attention to hygiene enable your 'Golden Lions' and your 'White Horses' to at length earn the respect of their patrons." According to an anonymous writer on the same subject the people who expectorate promiscuously in railway carriages, omnibuses, etc., are the chief offenders against decency and sanitation. Until women are allowed to dispense with skirts and appear uncriticized in rational costume, says this bold hygienist, they must, when making use of public vehicles continue exposed to the risk of soiling their petticoats with most offensive and dangerous filth. On a journey, women, he says, are generally encumbered with babies and parcels, and it thus becomes impossible for them to attend properly to their drapery when about to take their seats.

The Annual Report of the Chicago Health Department.—In the annual report for the year 1894, a table of the populations, total reported deaths and the death rates per 1,000 of population of all cities in the United States claiming to have population of more than 200,000 inhabitants showed Chicago to have the lowest rate. For the year just closed a similar table is given with the rates for 1894 appended for comparison:

	Claimed Population July 1, 1897.	Death Rate per 1000. 1897.	1894.
New York	1,990,881	19.5	21.0
Chicago	1,619,226	13.5	15.2
Philadelphia	1,214,256	18.8	18.3
Brooklyn	1,140,000	18.2	20.1
St. Louis	600,000	15.9	16.1
Boston	576,305	21.5	22.9
Baltimore	506,398	18.5	19.1
Cincinnati	500,000	14.3	18.3
San Francisco	360,000	17.1	18.8
Buffalo	360,000	12.5	16.7
Cleveland	350,000	14.2	15.8
Pittsburg	287,500	16.5	18.2
Washington	278,000	19.8	20.2
Detroit	275,000	15.0	15.5
Milwaukee	275,000	13.1	15.7
New Orleans	270,000	25.3	24.9

This is a most satisfactory showing of generally improved public health throughout the country during the past three

years—Philadelphia and New Orleans only showing no reduction of mortality. The rate of Chicago, 13.46 per cent. per 1000 is the lowest mortality rate ever recorded, so far as is known, for any city of more than 500,000 inhabitants, either in this country or in any other.

The principal reduction, and the one most gratifying is that in the deaths of infants and young children—fewer by 12 per cent. among the former, and by 12.5 per cent. among the latter, than during the previous year. Since there was nothing in the condition of the weather to account for this, it is only fair to attribute this saving of infant and child life chiefly to steadily improving sanitary conditions.

The result of this growing improvement is also seen in the marked diminution of deaths from the preventable diseases generally—diphtheria, typhoid fever, consumption, etc. The sanitary quality of the water-supply has averaged distinctly better than in 1896. To this better quality is largely due the reduction in the mortality from typhoid fever and the other impure water diseases. Some share of this reduction is undoubtedly due to the increasing care exercised by the public in the use of the hydrant water when it is found to be polluted. The daily laboratory examinations and the warnings based thereon are known to cause many persons to resort to boiling, or some other means of purification when the water is announced by the daily press to be "suspicious" or "bad." Fewer deaths from diphtheria have occurred during the year than in any other since 1884. Antitoxin in the treatment of diphtheria is probably used more freely and successfully by Chicago physicians than by any similar body of the medical profession elsewhere in the world. To their general, prompt and scientific employment of the remedy is to be ascribed the wonderful reduction in diphtheria mortality from an average of 35 per cent. prior to its introduction to 6.6 per cent. in nearly 4,000 cases coming under the direct observation of the Department. The inception of the antitoxin treatment of diphtheria by the Chicago Department of Health dates from the importation by the Commissioner in the fall of 1893 of 100 vials of the Behring serum. The remedy is now made available to physicians at a greatly reduced price and the Department further supplements their labors in the treatment of diphtheria by maintaining upward of a hundred antitoxin stations throughout the city for sub-laboratories for prompt bacteriologic diagnosis, and a corps of experts for assistance in various ways. In the laboratory 26,028 chemic and 3,919 bacteriologic examinations were made. Out of upward of 23,000 samples of milk and cream collected by the inspectors and analyzed in the laboratory, only 1,080 or 4.7 per cent. were found below grade. Through the inspections of the sources of the city's ice supply, including analysis of the waters of the ice fields, and the strict control of the disposition of impure ice made practicable under the permit system, there has been a great improvement in the quality of ice furnished for domestic use, and it is now almost impossible to deliver impure ice for domestic use without prompt detection. The Department meat inspectors have condemned approximately 2,000,000 pounds of meat as unfit for food, and supervised its destruction. Inspection of groceries and general food supplies has become a regular part of the laboratory work. The list now includes almost every variety of food products. Total mortality and mortality from principal causes during 1897 (compared with 1896): Total for 1897: All causes, 21,809; deaths under 1 year, 5,735; deaths from 1 to 5 years, 2,811; diseases of nervous system, 2,787; consumption, 2,180; pneumonia, 2,152; acute intestinal diseases, 1,386; violence, 1,410; diseases of the heart, 1,365; infantile diarrhea, 1,085; bronchitis, 1,026; diphtheria, 702; nephritis, 937; typhoid fever, 437; cancer, 773; other zymotic diseases, 542; other tuberculous diseases, 394; croup, 72; scarlet fever, 81. Total for 1896: All causes, 23,257; deaths under 1 year, 6,512; deaths from 1 to 5 years, 3,201; diseases of nervous system, 3,018; consumption, 2,310; pneumonia, 2,141; acute intestinal diseases, 1,859; violence, 1,362; diseases of the heart, 1,231; infantile diarrhea, 1,202; bronchitis, 1,165; diphtheria, 956; nephritis, 818; typhoid fever, 751; cancer, 734; other zymotic diseases, 517; other tuberculous diseases, 357; croup, 142; scarlet fever, 54.

ASSOCIATION NEWS.

The Senn Medal. Those members of the AMERICAN MEDICAL ASSOCIATION intending to compete for the medal offered by Dr. Senn for the best essay on some surgical subject, are requested to forward the type-written copies of contributions before March 1, 1898. Address,

J. McFADDEN GASTON, M.D., Chairman, Atlanta, Ga.

SOCIETY NEWS.

The Medical Society of the State of New York will hold its ninety-second annual meeting in the City Hall, Albany, N. Y., January 25, 26 and 27. The provisional program presents titles of thirty-nine papers.

Iowa State Medical Society.—The forty-seventh annual meeting of the Iowa State Medical Society will be held in Des Moines, Iowa, May 18, 19 and 20. The president is Dr. Edward Hornbrook of Cherokee; the secretary, Dr. James W. Cokenower of Des Moines.

Obstetrical Society of Claiborne.—The Society, at its annual election, chose the following officers: President, E. S. McKee; vice-president, W. D. Porter; recording secretary, Wm. Gillespie; corresponding secretary, M. A. Tate; treasurer, Geo. E. Jones; librarian, Dr. Bonfield.

Milwaukee Medical Society.—At the annual meeting of the Milwaukee Medical Society, recently held, the following officers were elected for the ensuing year: President, F. E. Walbridge; first vice-president, A. I. Comfort; second vice-president, John Madden; secretary, Gilbert E. Seaman; treasurer, U. O. B. Wingate; librarian, Louis F. Frank; curator, Arthur J. Patek.

MISCELLANY.

Action of Saliva on Bacteria.—Triolo states that filtered saliva has no bactericidal power, but that fresh sterile saliva will kill all the germs of staphyl. aureus, the bacteria of the air, of diphtheria, typhus, etc., in five day cultures, and greatly reduce their numbers in eighteen hour cultures.—*Gaz. d. Osp. e. d. Clin.*, December 12.

Anti-depopulation Measures.—A project has been presented to the French legislature that girl-mothers convicted of infanticide should be sent to some specially created colony and "condemned to one, two or three years according to the degree of criminality." His Excellency the Minister of the Interior is said to have taken the matter under advisement.

New Hints for Radiography.—Marcus states that iodoform, vaselin and iodoformed ether introduced into deep cold abscesses, form a mixture with the contents of the abscess impermeable to the Roentgen ray. Also that insufflation of air into hollow organs renders them perfectly transparent to the ray, which fact can be utilized in obtaining information in regard to the stomach, or the intestines insufflated from below, as they leave a blank space on the plate.—*Presse Méd.*, November 27.

Wanted.—We desire to secure a copy of No. 8, Vol. 21, of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for completion of above volume for a State Board of Health Library. Any of our readers having a duplicate of this number will confer a favor by returning same to this office and we will remit charges on same.

Necropsy of a Case of Pure Verbal Deafness. For four years the patient's only symptoms were the typic verbal deafness (inability to understand spoken words or to write from dictation), progressing then into sensory aphasia and death four years later. A double and symmetric poly-encephalitis was discovered in the temporal lobes, reduced one-half in size, diminishing in intensity from above downward and from the front backward. This was the only lesion and is the only case on record in which the lesion was purely cellular.—*Semaine Méd.*, December 22.

Nature of the Alterations in the Spinal Cord in Tabes.—Darkschewitch considers that the present status of our knowledge conflicts with the assumption that tabes is due to a primary affection of the cord. He attributes it to a preceding affection

of the peripheral nervous system of apparently varying character and varying localization. The alterations in the posterior column appears as the consequence of at least two morbid processes, a polyneuritis and a pachymeningitis in the ramification region of the art. spin. post. The affection of the lateral ventricles is apparently only the result of a polyneuritis.—Moscow Congress, *Wien. klin. Rundschau*, December 12.

Live Frogs as an Antithermic.—An English practitioner of Constanta, Roumania, writes: On the evening of October 19, I was called to visit a Roumanian boy, 6 years old, suffering from typhoid fever. I found him *in extremis*, almost pulseless. The child's head was completely wrapped over with a large white sheet, and as I looked at it this enormous white envelope seemed to be on the move and while I was surveying this covering there crept from under it a small frog, which quietly sat over the child's left arm. It seemed quite content. I immediately called the mother's attention to it and requested her to take the animal away, thinking it had crept there as an intruder. "Oh, no!" said the old lady, "a doctor recommended that a lot of them should be kept to the head to keep it cool." Seeing the head covering still on the move, I raised it for curiosity, and in a second out jumped about twenty other frogs and hopped away in all directions. I have often heard the expression "as cold as a frog," but this was the first time I had seen a frog applied as a head-cooler.—*London Lancet*.

The Address in Surgery Before the British Medical Association.—According to an editorial writer in the *British Medical Journal*, the recent presidential address of Mr. Mitchell Banks has fallen in divers errors about Ambroise Paré, errors that have been exploited beyond repair. That writer says, "Mr. Banks, will need to reconstruct his account of Paré. For all that Malgaigne says about it, the date of Paré's birth was 1509 or 1510, not 1517; nor did he 'lead an incessantly active life,' in the ordinary sense of the words, for the first few years after he was born. It is not probable that the Verdun story is genuine; there was no battle or siege of Rheims or of La Fère; he went to Dreux the day after the battle; and we do not know that he was at Saint Quentin or at Moncontour, or that he attended Charles IX. in his last illness. He did not write to his wife for ransom after the fall of Hesdin; it was M. Goguyer who wrote. He did not 'invent the ligature,' and never said that he did; he only invented the use of it in amputations; and he did not take for his motto that favorite saying of his *Je le pansay, Dieu le guarist*; the motto he chose for his own portrait in his books was *Labor improbus omnia vincit*."

The General and Special Hospitals of London.—A statistical statement issued by the Hospital Reform Association shows that in London the general hospitals have 5,349 beds, the special hospitals 3,475, and cottage hospitals 299, making a total of 9,123. The in-patients treated in one year were 62,774 in the general hospitals and 27,701 in the special. In the same year the general hospitals treated 897,389 out-patients and the special 439,338. Among the general hospitals the largest number of in-patients appertains to the London, where they amounted to 10,559; at St. Bartholomew's they were 7,290, at Guy's 6,325, and at St. Thomas' 5,493. St. Bartholomew's appears with the largest number of out-patients, 161,419. The special hospitals include five for diseases of the eye. For diseases of the throat, ear and nose there are six hospitals. There are five hospitals for diseases of the skin, six hospitals for diseases of the chest. The Hospital for Consumption has 320 beds and treated 1,851 in-patients during the year, the out-patients being 13,750. There are three orthopedic hospitals. For incurable diseases there are twelve institutions, having 611 beds, while the in-patients were 839, no out-patients being attended by these institutions. Hospitals for diseases of the nervous system are three in number. There are six hospitals for diseases of women and eleven for diseases of children. There are also six lying-in

hospitals and the hospital for cancer. Concerning the latter, the Middlesex Hospital has thirty-five beds set apart for the treatment of cancer, the patients being allowed to remain until they die.

The Toxin of the Gonococcus.—The *Annales de l'Institut Pasteur* for August, 1897, contain the results of an interesting series of experiments with the toxin of the gonococcus. It produces local and general phenomena, injected experimentally, with pronounced phlogogenic properties if injected into the eye or the pleura of the rabbit, while no effect follows its application on the mucous membrane of the conjunctiva or urethra. On the other hand, it produces in man a decided reaction in the urethra, transient but acute while it lasts. The urethra is not immunized by the process, as the same experience was repeated five times in succession. This reaction of the human urethra is special to the gonococcus toxin. Other toxins tested failed to produce any such result. Certain facts indicate that the toxin is located in the body of the coccus and liberated as it dies. It will stand heat to 70 degrees C., and is precipitated by alcohol. Attempts at immunization were successful with rabbits and goats. The serum of goats injected with increasing amounts of the toxin during the course of a year, rendered rabbits immune to the phlogogenic action of the toxin, which can then be injected into the eye and pleura without reaction. These facts have not yet been applied to therapeutics, but de Christmas hopes to obtain in time a serum powerful enough to arrest the progress of local gonorrhea and affect favorably the general phenomena caused by its toxin.

Presse Méd., November 27.

Temporary Gastrostomy for Cicatricial Stricture of Esophagus.—Villard, in reporting a case of the above character, expresses the opinion that we must not consider gastrostomy as a definitive procedure, but rather as a temporary measure, to give the operator time to adapt his means to his case, and to give rest to the esophagus, thereby suppressing the spasmodic and inflammatory condition of that organ and allowing the surgeon to resume the necessarily suspended catheterization. The following observation confirms these views: A woman, aged 45 years, had a cicatricial stricture for the past four years, due to ingestion of sulphuric acid. Regularly catheterized, this woman was fed through the esophagus until June, 1897, when, from unskilful catheterization, deglutition even of liquids became impossible. This woman, after ten days of absolute diet, was in a very bad general condition, weighing only thirty-nine kilograms—about seventy-eight pounds. Villard then performed gastrostomy in two sittings, and for nine days the patient was fed through the stomach. Esophageal catheterization then became again possible, as well as deglutition of liquids. From this on, regular dilatation of the esophagus was performed. Two months after, an operation was done to obliterate gastric fistula; autoplasty with three planes of suture; an insignificant fistulette, persisting for some time; complete cure in November; the patient had then gained eleven kilograms. At present she is fed by the mouth regularly and catheterized from time to time, so as to maintain the caliber of the esophagus. This is not, however, a unique case. In a report by Lefort, comprising sixteen patients, thirteen recovered, with a permeable esophagus after gastrostomy; and in one case of Jabouley of Lyons, gastrostomy performed almost in *extremis* enabled esophageal catheterization twenty days after, with a complete subsequent cure.—*Lyon Médical*.

Medico-Literary Notes.—A governmental report by Sir Richard Thorne, M.D., and Dr. Copeman, on the new preparations of bovine lymph, has been issued by the Local Government Board.

A Linnaeus wanted in chemistry.—Some change must soon be made in chemic nomenclature or a large portion of a lecture on chemistry will be occupied in articulating the name of the

subject which it is proposed to discuss. In a late number of the *Comptes Rendus*, MM. A. Haller and A. Guyot describe a new substance they have obtained which has the portentous title of the "tétraméthylidiamidodiphényldianthranoltétraméthyléidamidé symmetrical with the correspondent oxanthranol." This, we think, would be hard to beat even amongst German sesquipedalian words. The chemists want a Linnaeus.

Hirschwald's Medical Directory for 1898.—According to the directory the number of medical men in the German empire is 24,393, of whom 14,582 practice in Prussia, 2,612 in Bavaria, 1,785 in Saxony, 977 in Baden, 826 in Wurtemberg, 702 in Alsace-Lorraine. Of the large towns Berlin has 2,148 medical men, Munich 510, Hamburg 496, Breslau 432, Leipzig 379, Dresden 360, Frankfurt 288, and Hanover 218. Of the members of the profession residing in Berlin one qualified in 1830, one in 1841, two in 1842, two in 1843, and four in 1844, of whom Professor Virchow is one. The proportion of medical men to the population is 463 per 10,000 throughout the whole empire and 12.81 in Berlin.

"The Scholar in Medicine."—Dr. George Foy, of Dublin, has made a partial list, as he terms it, of the eminent names of medico-literary men who were natives of the British Isles: John Arbuthnot, author of "Scriblerius;" Wm. Barrington of Coleraine, founder of the Geological Society; Thomas Beddoes, the linguist; John Bell, whose work on Italy justifies his inclusion; J. Berkenhout of Leeds, author of the "Outline of the Natural History of Great Britain and Ireland;" Wm. Black of Belfast, author of the "Geyser and Rikam Springs in Iceland;" George Cheyne, author of "Physiological Principles of Natural Religion;" Erasmus Darwin, author of the "Phylogia;" Samuel Garth, translator of Ovid's "Metamorphoses;" Francis Glisson, the Aristotelian scholar; Samuel Gmelin, the scientist; Oliver Goldsmith, (?) the poet; John Gerard, the traveler and botanist; John Mason Good, the translator of "Lucretius;" William Musgrave, the antiquarian; Mungo Park, the African explorer; Thomas Percival, founder of the Manchester Philosophical Society; Sir Wm. Petty, author of the "Political Anatomy of Ireland;" Archibald Pitcairne, the mathematician; John Radcliffe, founder of the Radcliffe Library; Sir William Wilde, author of the "Valley of the Boyne;" William Withering, the mineralogist; John Wolcott, the satirist; William Woodville, author of the "Medical Botany;" Robert William, the antiquarian. Will not some of our readers undertake to compile a similar list for this Western world?

Arthurian Medicine.—Dr. G. M. Gould and W. L. Pyle have collaborated, for the Johns Hopkins Hospital Historical Club, a sketch of the medicine and surgery of King Arthur's time and of how the Knights of the Round Table fared after their many warrings and wounding. There is no mention in the Arthurian writings of a court physician. The sick and wounded were often taken to the nunneries, monasteries and to the abode of some hermit. Salves and ointments were used in the treatment of wounds, and the Sangrail was effective both for wounds and sicknesses. The bath medicated with herbs and phlebotomy were not unknown. Not only the religious inmates of nunneries but the noble women elsewhere undertook the dressing of wounds. The queen "la belle Isoud" was spoken of as "the noble surgeon."
